In order to capture children's competencies describing relations between known and unknown quantities, an exploratory design was created based on the representation of boxes and marbles (e.g. Melzig, 2013; Affolter et al., 2003). The concept of the tasks was to translate different kinds of equations with one or two unknowns into a representation that young children could handle. Known quantities were represented as marbles and unknown quantities were represented as boxes which contained an unknown number of marbles (see table 1). A story was told: "Here you see two children: Tino and Anna. They are playing with marbles. Some marbles are packed up in different colored boxes and some marbles are separate. Boxes with the same color always contain the same amount of marbles." The study includes 12 tasks of four different kinds. Kindergarteners got 10 of the 12 tasks, 2<sup>nd</sup> and 4<sup>th</sup> graders got all of them.

Type of task	Examples
A: "The same?": Children have to decide if both children have the same amounts of marbles or not.	A1: boy: $x + 1$ girl: $x + 2$
B: "How many?" (known): The children have to specify how many marbles are in a box so that both children have the same number of marbles. Children can answer with a specific number.	B2: boy: 4      girl: $x + x$ 
C: "How many?" (unknown): In type C a relationship between two unknowns can be stated.  Task C1: How many marbles have to be in the boy's box so that both children have the same amounts of marbles?	C1: boy: $y$ girl: $x + 1$ 
D: "Make them equal": Both children have the same amounts of marbles. The interviewer makes a transformation. Children have to decide what amounts of marbles they have to give to one child or take away to the interviewer, to make the quantities equal again.	D1: boy: $x + x$ girl: $y + y + 2$ à The boy gives one of his boxes ( $x$ ) to the interviewer. How much does the girl have to give to the interviewer?

**Table 1: Overview of the types of tasks used in the study. The variables in the last column represent the unknowns, which were represented as colored boxes. Each variable was represented with another color**

To get an insight into children's thinking, clinical interviews (Selter & Spiegel, 1997) were conducted. Various semi-standardized questions aimed to let children think more about the tasks. Each child worked on each of the tasks in an individual interview. The request "How did you get your answer?" helped to get an insight into children's way of thinking. The interviews were videotaped and transcribed.

## Analysis and results

After the transcription of children's answers, the diversity of children's solutions to the individual tasks was compiled. The tasks of type A were answered correctly by nearly all of the children. The correct answers of type B tasks varied between 40 to 72 % by kindergarteners, 72 to 97 % by 2<sup>nd</sup> graders and 92 to 97 % by 4<sup>th</sup> graders. Particularly interesting was the evaluation of the tasks of type C, where relations between two unknowns had to be established. The following presentation of results refers to the answers of the children to the task C1 (see table 1).

### Categories of the first answers

In task C1, the children were confronted for the first time with two unknown quantities. In contrast to the last task, no concrete value can be given. Therefore, the first spontaneous answers of children to task C1 are of interest. Table 2 presents the categories of children's answers.

Category:	Kinder- garten	2 <sup>nd</sup> grade	4 <sup>th</sup> grade
<b>State a relationship:</b> Children describe a relationship between the amounts of marbles in the boxes.	0%	4%	11,5%
<b>Describe a dependency:</b> Children describe that the amounts of marbles in both boxes depend on each other.	0%	12,5%	30,8%
<b>Numerical values:</b> Children mention values for the amounts of marbles in one or both boxes.	96%	58%	38,5%
... as examples: The values are meant as examples.	12,5%	57%	90%
... as fixed values: The values are meant as fixed numbers.	41,6%	29%	10%
... not to classify exactly: At this point of analysis, it is not clear if the mentioned values are meant as examples or not.	45,8%	14%	0%
<b>Unintended answers:</b> The children interpret the task differently. E.g. children want to change the amounts of given marbles in the task to give an answer.	0%	12,5%	0%
<b>No answer:</b> Children give no answer.	4%	8%	7,7%
<b>Not possible to evaluate:</b> The answers of the children cannot be evaluated more precisely at this point.	0%	4%	11,5%

**Table 2: Categories of children's first spontaneous answers to task C1**

The overview shows that most children first enter numerical values for the content of the green box. But there are also clear differences between different age groups. While the majority of kindergarten children indicate numerical values, some children in grades 2 and 4 are already able to describe relationships or dependencies. Of particular importance at this point are the interviewer's following requests, which encourage children to overlook different numerical values and consider the relationship of possible numbers of marbles in the boxes. This is especially the case with some children, who initially cannot answer, but often show a deep understanding of relationships in the process of the interview. It can be assumed that the children were unaware that "a marble more" may be an appropriate answer.

### **Further data analysis**

The answers of the children after the requests of the interviewer were very different. Since the task design suggests making relationships between unknowns, the children's responses can be categorized in two directions: establishing relationships and dealing with unknowns, whereas the boxes had to be interpreted as variables. Regarding relational thinking, there are three ways to recognize relationships (children describe a relationship or display the dependency or neither describe a relationship nor a dependency). Regarding the question how children handle the unknown quantities, there were two ways to get the categories: first in a deductive way, because the theoretical framework gave various categories about aspects of variables (as unknowns, as a general number, as a variable, and as a quasi-variable); secondly, the categories are found in an inductive way, because the data also revealed categories that could not previously be found in the theoretical framework. These were interpretations of the boxes as an absolute number and undeterminable.

### **Children's answers regarding relational thinking**

Some children directly describe a relationship between the two unknown quantities as in types of task C (table 1). The 4<sup>th</sup> grader Luca said: "In the green box is always one marble more than in the orange box". Other children describe that the two unknowns depend on each other, but without describing the relation more precisely. The 4<sup>th</sup> grader Kathy answered: "It depends on how many marbles are in the orange box". Other children neither describe a relationship nor describe a dependency between the amounts of marbles in the boxes. There are very different answers in this category. Some children mentioned specific quantities or wanted to shake the boxes to find out how many marbles are in them.

### **Children's answers regarding the understanding of the represented unknown quantities**

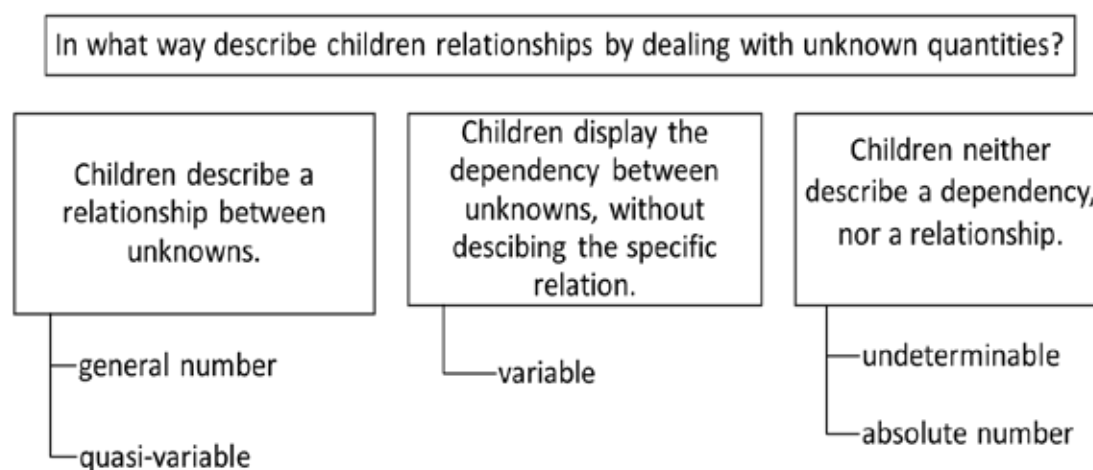

Children have very different answers by describing the unknowns in tasks of type C. These different types of understanding the unknown quantities are the following:

The unknown amounts of marbles in the boxes as a *general number*: children see the amounts of marbles in the boxes as an unknown, indeterminate number, which cannot be determined and therefore has to be stated as a general relationship. The 4<sup>th</sup> grader Luca says: "In the green box is always one marble more than in the orange box". The unknown amounts of marbles in the boxes as *quasi-variables*: children describe the general relationship between the amounts of marbles in the boxes with the aid of examples. The difference to the former is less in the recognition of the relationship than in the linguistic expressiveness. The 6 years old kindergartener Adam says: "...if there are eight or nine marbles in the orange box, then I take one marble more, that's nine or ten marbles for the green box". The unknown amounts of marbles in the boxes as *variables*: children

describe the dependency of the amounts of marbles between the different colored boxes. Children say that there is a relation, but they do not specify it. In contrast to the interpretation as a general number, the dependence of both values is indeed recognized, but cannot be described as a fixed relation. Although the children are able to assume different values for the number of marbles in the boxes, they are not able to give a general relationship. The 4<sup>th</sup> grader Anton says: “There are various possibilities because I don’t know how many marbles are in the orange box”. The unknown amounts of marbles in the boxes as an *absolute number*: the children give a specific number of marbles, sometimes without considering the amount of marbles in the other box. The kindergartener Clara says: “Four. Because the box is so small, there just fit four marbles in”. The unknown amounts of marbles in the boxes as an *undeterminable*: This category results from the empirical data and finds no equivalent in the theoretically elaborated aspects of variables. Children who see the unknown amounts of marbles in the boxes as an undeterminable answer that the amounts of marbles in the boxes can’t be determined without to open it. The 2<sup>nd</sup> grader Rob answers: “I have to open the box”.

### Putting both together: Relational thinking and understanding unknown quantities

The design of the tasks allows putting both dimensions together: relational thinking and the understanding of unknown quantities. The following evaluation schema shows all the combinations found in the data. They indicate that the two dimensions are intertwined. Children who describe relationships between the unknown quantities understand them as either a general number or a quasi-variable. Children who describe dependency take the unknown quantities as a variable. Children who neither establish a relationship nor describe a dependency understand the unknown quantities as either an absolute number or an undeterminable. The interviewer's requests encourage the children to think more profoundly about the tasks<sup>1</sup>. After requests of the interviewer, 12% of the children in kindergarten describe a relationship between the unknown quantities and describe them as a general number. This increases to 17% in the second grade up to 73% in the fourth grade. 12% of kindergarten children describe a relationship with the help of quasi-variables. This is also the case for almost 17% of 2<sup>nd</sup> graders and almost 4% of 4<sup>th</sup> graders.

**Figure 1: Evaluation scheme**

<sup>1</sup> Case studies and their application to the evaluation scheme can be viewed in Lenz (2016) and in Steinweg, Akinwunmi, & Lenz (2018).

It should be mentioned that the fields shown in the evaluation scheme are not to be seen as a fixed classification of individual children. Rather, the analysis scheme describes a single answer in the course of the interview and is not seen as a stable attribution to a child.

## Conclusion

The analysis indicates that the task design is actually designed to encourage children to establish relationships between unknown quantities. Particularly interesting is the transition between task types B and C which seems to be a special breaking-point in the use of variables. The role of the unknown amounts of marbles in the boxes changes from an unknown that can be determined to a variable whose value cannot be known but can be described as a relation. It must be distinguished in which way the children interpret the unknown number of marbles in the boxes.

The evaluation scheme allows two dimensions of algebraic thinking to be linked: relational thinking and understanding unknown quantities. The analysis has shown that children from the age of 5 years old as well as primary school children are able to show relational thinking about unknown quantities. However, there are also children who understand the number of marbles in the boxes as an absolute number. A possible reason for this might be due to the concrete representation of the boxes. It is important to investigate whether this would be still the case of representing photos of the tasks. A difficulty is to see in the limitation of the linguistic expressiveness of the children. In particular, the children of the kindergarten found it difficult to express their thoughts in words. They often made gestures and facial expressions to help, which requires further investigation. On an active level, all children have the opportunity to get started with the tasks. Although the task design looks very simple, it allows for variation in primary school and secondary level. For example, tasks with limit value determination or case distinctions can also be created. The design allows continuing these tasks on a formal level. Placeholders, symbols, or letters can replace the boxes. This study can be seen as a starting point to develop classroom lessons that allow relational thinking in elementary school mathematics lessons and a first approach to dealing with different variable aspects. The common exchange in the classroom can be seen as particularly profitable.

<sup>2</sup> Instituto de Educação, Universidade de Lisboa, Portugal; jpponte@ie.ulisboa.pt

*The aim of this paper is to understand how a path of teacher's actions leads to students' generalization. Generalization, as a main process of mathematical reasoning, may be inductive, abductive, or deductive. In this paper, we focus on an abductive generalization made by a student. The study is carried out in the third cycle of design of a design-based research involving lessons about linear equations in a grade 7 class. Data is gathered by classroom observations, video and audio recorded, and by notes made in a researcher's logbook. Data analysis focus on students' generalizations and on teacher's actions during whole-class mathematical discussions. The results show a path of teacher's actions, with a central challenging action, that allowed an extending abductive generalization, and also a subsequent deductive generalization.*

**Keywords:** Generalization, Abductive reasoning, Mathematical reasoning, Teacher's actions.

## Introduction

Generalizing in algebra is a highly relevant aspect of mathematical teaching and learning as it is an essential part of algebra (Kaput, 2008). In addition, generalizing is a central mathematical reasoning process. As such, what the teacher does in the classroom to enhance students' generalizations is of great importance. To enhance students' mathematical reasoning in the classroom, and hence generalizations, involves setting a challenging learning environment that goes beyond proposing exercises to solve using well-known procedures. In this research, we address mathematical whole-class discussions, unleashed by exploratory tasks (Ponte, 2005), as privileged moments to promote students' mathematical reasoning. Seeking to develop knowledge about how teachers can help students to engage in mathematical reasoning, we conduct a design-based research (Cobb, Jackson, & Dunlap, 2016). In this paper, we focus on a specific situation of the third cycle of design, aiming to understand how a path of teacher's actions, supported by design principles that focus on generalization, lead to students' generalization, particularly in a case of an abductive generalization.

## Mathematical reasoning

There are several definitions of mathematical reasoning, but most of them gravitate around the idea of making justified inferences (e.g. Aliseda, 2003; Pólya, 1954; Rivera & Becker, 2009). What differs in those various definitions is the path that takes place from prior knowledge to new knowledge. As such, the perspectives on mathematical reasoning accommodate both logical and intuitive aspects, providing a scope that includes deductive, inductive and abductive inferences. Deductive inference, characterized by a logic perspective, has two main characteristics: (1) certainty, that refers to the necessary relationship between premises and conclusion, where the conclusion follows necessarily from a set of premises, and (2) monotonicity, related to the irrefutability of conclusions, i.e., a valid inference remains valid when additional premises are added (Aliseda, 2003). Deductive inference, despite being often presented as the paradigm of mathematical reasoning (Aliseda, 2003) is not

necessarily the single path to carry out mathematical reasoning. There are other rigorous forms of reasoning, such as inductive and abductive inferences (Jeannotte & Kieran, 2017; Rivera & Becker, 2009), although they do not provide the same certainty and irrefutability as deductive inferences (Aliseda, 2003). Russell (1999) stresses that mathematical reasoning consists in thinking about properties of a mathematical object and developing generalizations that apply to a broad class of objects, thus underlining the inductive aspect of mathematical reasoning. On one hand, inductive inferences occur essentially when predictions are made or conjectures are formulated (Aliseda, 2003), and are also associated with generalization from the identification of a certain characteristic common to several cases (Rivera & Becker, 2009). On the other hand, abductive inferences have mainly an explanatory role, but also have a knowledge-building role. Thus, abductive inferences aim to construct hypotheses for unknown phenomena, being a reasoning used to explain something intriguing (Aliseda, 2003) or to discover something (Magnani, 2001). In this sense, abductive reasoning is identifiable with the formulation of a generalization based on relations between aspects of a given situation and its conclusions are plausible in the context of the situation (Rivera & Becker, 2009).

### **Generalizations**

Given its complex nature, mathematically reasoning involves a variety of processes that are evidenced in the students' individual thinking and sense making, in their classroom work, and in the interactions that take place during whole-class discussions (Brodie, 2010). These processes include formulating questions and solving strategies, formulating and testing generalizations and other conjectures, and justifying them. From these reasoning processes, we hereby highlight generalization as a key process of mathematical reasoning and, hence, of algebraic thinking. Generalizing, by stating that an idea, property or procedure is valid to a given set of objects (Dörfler, 1991; Ellis, 2007), is the basis of many mathematical ideas and concepts. On a day-to-day basis, students are naturally predisposed to generalize (Becker & Rivera, 2005). However, it is important to note that in the classroom, generalizations may be incorrect or only implicit presented (Becker & Rivera, 2005; Reid, 2002). Thus, to promote students' mathematical reasoning, it is necessary to create situations in which generalization plays a central role (Kieran, 2007), in order to lead students to present generalizations based on mathematical ideas, concepts and properties.

Generalizations that students present or use in the classroom may emerge from different approaches and at different levels. To develop the capacity of formulating generalizations, both in empirical and deductive approaches, students may act at three levels: factual, contextual and symbolic (Radford, 2003). Factual generalization comes from empirical observation or particular cases that are applied to new cases in the same set of mathematical objects. Contextual generalization, also based on empirical observation or particular cases, presumes an extension to a new set of mathematical objects. Symbolic generalization emerges from the use and understanding of symbolic language. Within this scope of levels, students' generalizations may emerge from (a) relating, when students create a relation or make a connection between situations, ideas or objects; (b) searching, when students search for an element of similarity, or (c) extending, when students go beyond the situation or case, which originated the generalization (Ellis, 2007). Moreover, as highlighted by Jeannotte and Kieran (2017), generalizing is a process related with the search for similarities and differences. As such, when a student generalizes, it is possible to identify either a continuing phenomenon, an element of

sameness, or a general principle (Ellis, 2007). Generalizations refer to a continuing phenomenon when the students identify properties that go beyond a particular instance. When an element of sameness is at stake, the students identify either a common property, the same objects or representations or the same situations. Regarding generalizing by stating a general principle, the students may identify general rules, patterns, strategies and global rules.

### **Teacher's actions during whole class discussions**

To promote generalization at different levels, and subsequently to contribute to students' competence of a proper use of inductive, abductive and deductive reasoning, teacher's actions are a central aspect. These teacher's actions to promote mathematical reasoning in the classroom should consider the different moments of the lesson. In lessons framed by exploratory teaching (Ponte & Quaresma, 2016), whole-class discussion moments that stand out as very promising to enhance students' mathematical reasoning (Ponte, 2005). Ponte, Mata-Pereira, and Quaresma (2013) identify four main categories of teacher's actions that can be distinguished during whole class discussions and that are directly related to mathematical processes: (i) inviting actions – leading students to engage in the discussion, (ii) guiding/supporting actions – conducting students along the discussion in an implicit or explicit way in order to continue the discussion; (iii) informing/suggesting actions – introducing information, providing an argument or validating students' interventions; and (iv) challenging actions – leading students to add information, provide an argument or evaluate an argument or a solution. Guiding/supporting, informing/suggesting, and challenging actions, are main supports to develop whole class mathematical discussions, and involve key mathematical processes such as (i) representing – provide, revoice, use, change a representation (including procedures), (ii) interpreting – interpret a statement or idea, make connections, (iii) reasoning – raise a question about a claim or justification, generalize a procedure, a concept or a property, justify, provide an argument, and (iv) evaluating – make judgments about a method or solution, compare different methods.

### **Methodology**

This paper reports part of the third cycle of a research study that follows a design-based research (Cobb et al., 2016) aiming to develop a local theory about enhancing students' mathematical reasoning in the classroom. Before this third cycle of design, a first cycle took place in lessons about sequences and a second cycle in lessons about linear equations. In order to achieve the overall aim of this research, we establish a set of design principles (Cobb et al., 2016) based on the literature and on previous cycles of design focusing on tasks and on teacher's actions to enhance students' mathematical reasoning, particularly emphasizing generalizing and justifying. Due to the focus of this paper, here we specifically focus on three principles for teacher's actions that aim to enhance students' generalizations, indicating that the teacher should (a) promote situations that prompt students to share ideas, namely considering and valuing invalid or partially valid contributions, deconstructing, complementing or clarifying them, (b) support or inform students in order to highlight reasoning processes, particularly generalizing, and (c) challenge students to go beyond the task.

The episodes reported in this paper took place in a Portuguese public school in a grade 7 class with 27 students (12-13 years old), and involved nine lessons about linear equations. These were students' first approach to equations, and connections between functions and equations had not yet been

addressed. The particular episodes presented are from lesson 3 and lesson 6 and regard the number of solutions of a linear equation, with a specific focus on equations with no solutions. The main goal of lesson 3 was to introduce the property of invariance of equality by multiplying and the proposed exploratory task included solving an equation in order to generalize this property. In lesson 6, the main goal was to discuss the number of solutions of an equation, particularly in impossible equalities. In order to do this, students are proposed to solve some equations, including  $3x + 6 - x - 15 = 2x + 9$ . Both lessons were directly observed and video and audio recorded, and notes were made in a researcher's logbook. A detailed plan of each lesson, prepared by the first author and discussed in detail with the teacher, was made attending to the tasks to propose and considering teacher's actions to enhance students' mathematical reasoning. The participating teacher was selected because of her experience, commitment to professional development, and availability to consider changes in her practice. All participants in this study are volunteers, have fictitious names and have given their informed consent to participate. Data analysis is centered on students' generalizations and focus on the design principles and the conceptual framework regarding teacher's actions.

### **An unexpected generalization**

After a whole class discussion about the task that aimed to introduce the property of invariance of equality by multiplication, the teacher begins to register this property on the board. However, while writing down the property, the teacher realizes that during the discussion, the exception of zero was not taken into account. As such, she poses a question to students, regarding possible exclusions:

Teacher: Let us register the multiplication property of equality that says that, if one multiplies or divides each member of the equation by the same number... Any number? Or do I have to ensure something? If we multiply or divide both members of the equation by the same number, my question is, by any number? Or is there any number that I have to exclude?

As the task that students had previously worked on and discussed did not include any question regarding this exclusion, by posing this question to students, the teacher is *challenging* them to go beyond the proposed task (principle c). This question receives an immediate answer from Clara, one of the students. However, the teacher decides on going further on the discussion by *challenging* students to present for a justification (principle c).

Clara: Zero.

Teacher: Why?

Gabriel: Because it is neutral, is neutral! Is the neutral element.

Gabriel provides an invalid justification based on his previous knowledge of the formal properties of operations. At this point, teacher opts on *guiding* students to deconstruct the invalid statement (principle a):

Teacher: Easy there, is the neutral element of which operation?

Several students: Addition.

Teacher: But are we talking about addition?

- Leonardo: Oh, no, is about multiplication.
- Teacher: Is the... Element, how is it called?
- Gabriel: Neutral!
- Leonardo: No, is the one that absorbs everything.
- Clara: Absorbing.

After some students' interventions, one of them presents a justification that is considered by the teacher as being partially correct. However, the teacher keeps *guiding* students in order to go further on their justification (principle a).

- Teacher: Absorbing element. So, can I... Can I divide by zero?
- Several students: No.
- Teacher: No, it doesn't make sense. Can I multiply? What is the problem of multiplying both members by zero?
- Several students: Is going to be zero.
- Teacher: I will get zero equals zero and I will not be able to move forward. So, [continuing to write the property] distinct from zero, the solution-set is preserved.

At this point of the discussion, the teacher *informs* students in order to conclude the introduction to the multiplication property of equality (principle b).

After clarifying why zero has to be excluded in this property, and straight after writing down the property, Clara asks to intervene:

- Clara: Teacher, I don't know why, but after you wrote down that [the property of invariance of equality by multiplication] I believe... I have this feeling that not all equations have a solution.

Supported by the property of invariance of equality by multiplication, Clara *generalizes* that not all equations have a solution. In this generalization, Clara relates aspects of the property that is being discussed with what she knows so far about equations, without relying on a particular example, presenting an abductive generalization. By its relations to the particular property and also by expanding its scope, this generalization is a general principle of a contextual and extending nature. This was not an expected generalization at this moment, however, the teacher *challenges* Clara to elaborate on her statement (principle c).

- Teacher: Why did this [multiplication property of equality] lead you to believe that not all [equations] have a solution?
- Clara: I don't know, but...
- Teacher: But I got curious, why did anything that I have said here...
- Clara: I do not know it myself... I think it is because of zero... I don't know, but I get the feeling that not all of them have. . . .

Teacher: Look [Clara], hold back, if necessary take a register . . . Stating that this made you think that it might have equations that do not have a solution. When we discuss this issue, that won't be right now, we will see.

As Clara cannot go further on her justification, the teacher begins by *challenging* this student again to present a justification (principle c), but then quits to obtain such justification and *informs* the class that Clara's idea will be discussed later.

### Validating Clara's generalization

A few lessons after, the teacher proposed a task to students in order to introduce the classification of linear equations according to the number of solutions. While the students were solving an equation proposed in the task using the properties of equality, the equation  $0x = 18$  emerged, triggering the discussion that follows:

Leonardo: But that will keep having an infinity of solutions.

Teacher: Will it?

Leonardo: Oh, no, no, it won't work for every number.

Teacher: Won't work for every number? . . .

Leonardo: No, because no number times zero equals 18! . . . So, isn't this a false equality? Is, isn't it? This is a false equality, because any number times zero will equal zero.

Teacher: And?

Gustavo: This one doesn't have a solution, teacher. . . Is impossible! . . .

Leonardo: So, this means that there are equations with no solution!

As a previous equation of the task had infinite solutions, Leonardo wrongly *generalizes* that this equation also has it. By being wrong, this generalization is factual and of a searching nature, as the student considers that it belongs to the same set of mathematical objects, looking for an element of sameness. However, instead of telling the student that he is wrong, the teacher *challenges* him to evaluate his statement (principle a), which he properly does. Once more, the teacher questions the student *challenging* him to justify his statement (principle c), which he does. By *guiding* the student to continue (principle a), students *generalize* that there are equations with no solutions, based on the example of the equation that they are working with. This generalization, by going beyond the previous set of mathematical objects is of a contextual level and has a relating nature. Moreover, it refers to a continuing phenomenon as it identifies a property that does not apply only to this particular instance. After concluding this segment of the discussion, Clara intervenes, recalling that she had already stated this generalization:

Clara: Teacher, do you remember that lesson in which I had... That thing that we had regarding the multiplication property of equality, that I said that... Because I hear about zero and it was...

Teacher: Exactly, it was because of zero. That is why I asked you what made you think [that]. Because it was when we talked about zero that you did that observation. . .

Clara: It was because of zero, but I couldn't [explain].

At this point, teacher *informs* that it was valid and that the argument was also correct, despite incomplete, as Clara was not able to justify her statement (principle b).

## Discussion and conclusion

Generalizations on both episodes emerged from a path of teacher's actions with a central challenging action. These paths include this central action followed by other challenging actions or by guiding actions and end up with an informing action from the teacher. These teacher's actions are strictly related to the design principles of the study as challenging. Guiding actions mostly relate to situations where a partially valid or invalid contributions emerge or to situations where the students are challenged to go beyond what was initially proposed. In addition, informing actions have a relationship with situations where the teacher highlights a generalization.

Whereas the paths of actions oriented by the design principles lead, in both episodes, to generalizations, the nature of the generalizations that emerged is not the same. In the first episode, Clara, supported by the discussion around the property of invariance of equality by multiplication, presents an abductive generalization as she relates aspects of the situation being presented, despite not being able to justify her statement. This generalization, is a contextual and extending generalization of a general principle. As Ellis (2007) indicates, this type of generalization is what researchers seek. In the second episode, the valid generalization that emerges is more deductive. This generalization, by its logical form, only needs an example to be valid. As such, the students properly realize that not all equations have a solution. This generalization, despite also being of a contextual level, is considered as a relating generalization of a continuing phenomenon.

This study shades light to what generalizations of different nature can look like in the classroom and particularly on what paths of teacher's actions can lead to such generalizations. In doing so, the framework for teacher's actions proposed by Ponte, Mata-Pereira, and Quaresma (2013) as well as the design principles have a central role. Another aspect highlighted by this study is the idea that developing algebraic thinking does not have to be immediate, as this competence should include the intellectual patience to embrace a partial understanding and the confidence that, with future actions, knowledge will advance (Arcavi, 2007). As such, not only opportunities for deductive generalizations should be considered, but also there should be opportunities for students to generalize abductively and inductively.

*This paper focuses on the emergence of abstraction through the use of a new kind of motion detector — WiiGraph — with 11-year old children. In the selected episodes, the children used the sensor to create three simultaneous graphs of position vs. time: two graphs for the motion of each hand and a third one corresponding to their difference. They explored relationships that can be ascribed to an equation of the type  $A - B = C$ . We propose two distinct paths for the attainment of abstraction, one focused on working with unknowns lacking sensible qualities, and another that involves navigating a surplus of sensible qualities. This study is a case study for the latter, which we portray as a process of opening channels of flow and exchange among sensible qualities, such that these cease to be self-enclosed and start to configure a plane of unity, which, far from denying their differences, brings them into mutual circulation.*

**Keywords:** Body motion, sensors, early algebra, abstraction.

### Introduction

Learning mathematics is often seen as a progression from the concrete to the abstract. This progression amounts to a passage across emphases, from the sensible to the intelligible. An archetypal example is that of the straight line. Out of countless acts of drawing, touching straight edges, tracing on the sand, or using tools, a sense grows for physical straightness. There is still a major gap between the latter and a geometric straight line involving a massive drawing out of sensible qualities, such as color, length, material, and thickness, to envision an entity that is intelligible but not sensible. Hence abstraction is depicted as a subtractive process, along which more and more qualities are taken out until a spectral remainder is left that is not amenable to being touched, seen, or heard, and is devoid of causal powers, whose presence is only indirectly evoked by diagrams and formulae. Numerous researchers in mathematics education have questioned this traditional image for the attainment of abstraction (Clements, 2000; de Freitas, 2016; Dreyfus, 2014; Hershkowitz, Schwarz, & Dreyfus, 2001; Noss, Hoyle, & Pozzi, 2002; Roth & Hwang, 2006).

Concluding his commentaries about multiple mythical narratives, such as the one of Thales measuring the height of an Egyptian pyramid by the shadow of a stick, or the use of the gnomon in ancient Babylonia, Serres (2017) insists: “Yes, its abstraction is a sum and not a subtraction” (p. 210), and introduces the image of white light: “Geometry integrates all our practical or ideal

---

<sup>a</sup> All authors contributed equally to the article

habitats the way white light sums up all the colors, in transparency or translucency” (p. 210). This remark has inspired us to distinguish paths for the realization of abstraction corresponding to white and black light. Whereas the path of black light is abstraction by means of subtraction of sensible qualities, the path of white light meanders in the midst of a *surplus* of sensible qualities. In this paper, we aim at investigating a particular case of the pursuit of abstraction along a path of white light.

## Generals and Unknowns

To illustrate the difference between abstracting paths of white and black light we invoke Peirce’s distinction between a general and an unknown. Let us start with the notion of a general:

A sign is objectively general, in so far as, leaving its effective interpretation indeterminate, it surrenders to the interpreter the right of completing the determination for himself. “Man is mortal.” “What man?” “Any man you like.” (Peirce, 1994)

A theorem proving a property of triangles, for example, deals with triangles as a general. A general is genuinely indeterminate, which makes the logic principle of the excluded middle invalid: Is the triangle isosceles?: no; is the triangle not-isosceles?: no. In contrast to generals, Peirce characterized unknowns — particulars with certain but unspecified traits — as “vague.” We are uncertain whether the eye color of a friend is green or brown, but we know that it is not, say, red. The vagueness of her eye color includes infinite shades of brown and green and excludes redness. Together with such vague sense of eye color, we may also presume that her eyes are of a particular color, which is the key character of an unknown: its traits are determined but we know them only vaguely.

Grappling with an unknown entails relating to an entity that lacks, perhaps only momentarily, certain sensible qualities both in itself (e.g. her eye color) or in its signs (e.g. a textual description of her eye color). On the other hand, we navigate a general, such as mortals or triangles, by immersing ourselves in a vast and familiar terrain of sensible variations and differences, such as mortals of different age, sex, species, bodies, and behaviors; or triangles differing in shape, size, angles, perimeters, and colors. The question we strive to address in this study is precisely: What kind of navigation arrives at abstraction across a *surplus* of sensible qualities, that is, of the white light type (in terms of generals)? We examine this question through selected episodes in which children explore the kinesthetic production of graphical expressions, for a general that can be named by the equation:  $A - B = C$ . We situate our study within the growing field of early algebra (Kieran, Pang, Schifter, & Fong Ng, 2016). The emphasis of the early algebra work tends to be on the logic of unknowns and on generalizing processes with respect to patterns, variables, structures and relational thinking (Blanton et al., 2016; Bodanskii, 1969/1991; Carraher, Schliemann, Brizuela, & Earnest, 2016; Kaput, 2008; Kaput, Blanton, & Moreno, 2008; Ng & Lee, 2009; Radford, 2014). While generals are different from the recursive-empirical reasoning often associated with generalizing, they are also significant in the early algebra literature (see Bodanskii, 1969/1991, which discusses Davidoff’s vision of early algebraic thinking — perhaps the closest to engaging children with generals). The work described in this paper belongs to early algebra, we suggest, because algebra can be taken to be the symbolic treatment of unknowns and generals

## Sensors, Kinesthesia and Method

In this paper, we attend to the kinesthetic production of graphical expressions by means of a particular mathematical instrument. By “mathematical instrument” we refer to a material implement used interactively by means of individual or collective continuous body movements, to obtain and transform mathematical expressions (Nemirovsky, Kelton, & Rhodehamel, 2013). “WiiGraph” is a mathematical instrument we have used in our study. Among its many possible settings, there is one in which the distances between two hand-held Wiimotes (remotes) and a LED sensor bar are graphed over time, while a third graph, corresponding to the differences between these two distances, is also displayed in real time. The color of each position vs. time graph corresponded to the color of the Wiimote being recorded (i.e. light blue and pink; the presence of two large dots with these colors on the screen indicates the sensor as connected to the Wiimotes), or a different one for the case of the difference graph (i.e. dark blue; see Figure 1). WiiGraph belongs to a family of mathematical instruments based on motion detection, which work at body-scale involving wide body movements like walking or overarm gestures and are responsive to two movements occurring simultaneously, whether performed by one or two people at a time.

**Figure 1: A child generating two position vs. time graphs and their difference graph**

In the study, we worked with a group of four children aged 11 years, who did not previously know each other, over three sessions. The children had been recruited as volunteers through a network of families practicing home schooling education. They do not attend regular lessons at school, therefore we cannot infer about their mathematical background. The participants were filmed with two fixed cameras during each session and two of them wore a head-based Go-Pro camera. During the first two sessions they explored position vs. time graphs generated by two children, each moving a Wiimote. In addition to free explorations, they engaged in diverse activities anticipating and matching body motions and graphical shapes of position vs. time. In the third session three children worked by holding both the remotes individually, one remote in each hand. As opposed to a pair of children each handling one Wiimote, the one-in-each-hand arrangement differs markedly, among other reasons because of the centrality it confers to relative arm motion (Nemirovsky, Kelton, & Rhodehamel, 2012). The instructor chose to turn on the difference graph, displayed in dark blue, as a significant way of exploring relationships between graphs symbolically, beginning the episodes we examine in the next section. We have selected these episodes because they span the students’ production and exploration of the difference graph. The first two authors were both present in the episodes (respectively, RN and NA below; D, M and Z refer to the children).

## Selected Episodes

### Episode 1: Introducing the difference graph and trying to keep it on zero

RN: (...) the computer also generates another line [turns on the difference graph] that is, em, dark blue, [points at the dark blue graph; Figure 2] (...) so we'll investigate what this third line is doing there, what it is showing. So the first thing we will try...

M: It's called, it's called minus because that, that purple [dark blue] line, line is, is, is pink minus blue.

RN: OK, how do you know that?

M: It's real, it's quite obvious, where it says pink minus blue [points to the screen, note the area pointed at with a black arrow in Figure 2] at the top of the screen.

RN: Aha (...) So you move [showing the Wiimotes to move with], you do whatever you want, [moves alternately right and left hands] but try to keep the dark blue on zero [points to the dark blue line], on this line [left hand runs along the  $x$  axis].

**Figure 2: Graphical display in which the dark blue difference graph is displayed for the first time**

M begins his first difference graph: he starts with the pink remote in his left hand and the blue one in his right hand. At the beginning of the experiment, the pink remote is kept slightly ahead of the blue one, and then the two are slowly switched in their positions. Holding the two remotes separated, he then walks forward (see Figure 3).

**Figure 3: M's first attempt to create a difference graph**

During the last seconds of the graph production (see Figure 3), he says:

M: I'm trying as hard as possible not to make the things go opposite.

## Commentary

The appearance of a third graph prompted M to examine the screen seeking for additional signs that could name or account for it. There was none with a dark blue color. However, the sign at the top of the screen “pink minus blue,” which had been displayed from the beginning of this session but had remained unused, offered him a compelling interpretation (“it’s obvious”): the dark blue line “it’s called minus.” Besides the two remotes with clear referents, the minus was a third component, which was immediately clasped by the third graph. The dark blue graph seemed to announce its name. M was eager to be the first to use WiiGraph to obtain a dark blue graph that remained on the horizontal axis. M generated the graph shown in Figure 3 slowly moving the pink and blue Wiimotes back and forth in opposite directions. He seemed to move his arms exerting an effort, as if he had to push them back and forth. Perhaps RN’s prior example, in which he had moved his arms in that way, had tacitly suggested to M that this is the kind of motion to perform. However, upon seeing that the dark blue graph refused to stay on zero, except for an interval around the 7<sup>th</sup> second, his arms tensed as if trying to push the dark blue graph to the center. M reflected on this sense of effort (“trying as hard as possible”) as striving “not to make the things go opposite”. Among other possibilities, this “going opposite” might have been the dark blue graph shifting in a direction opposite to the desired one. This episode suggests how the kinesthetic interpretation of a symbolic expression that we would consider algebraic (i.e. pink minus blue) is not “given” on its own, but demands novel interpretive acts involving matters of a qualitatively different nature, such as the fastness and slowness, or the proximity and remoteness, of his hands. A pattern of motion is not there to be seized, but needs to be created. The use of WiiGraph incorporates body motion — a complex realm of sensibility and performance — to generate graphical shapes, dramatically broadening the sensory qualities at play in obtaining intended and unintended graphical shapes. Furthermore, kinesthesia inherently awakens bodily feelings. How is a minus responsive to kinesthetic actions? In our interpretation, the graph called minus was not just a visual display out there, but also a curve that resisted physical efforts seeming to possess a will of its own.

### Episode 2: D works with the difference graph

After M obtained several additional graphs, he gives the Wiimotes to D, who starts a new graph. He stands still in the same position for all the session, keeping steadily the remotes at the same distance from the sensor (See Figure 4).

**Figure 4: D generates a graph staying still with the Wiimotes next to each other**

RN: So that, that’s a perfect zero [around the 8<sup>th</sup> second, everyone laughs]  
[ending his graph, D relaxes his position, shrugs his shoulder and smiles].

NA: This is one way to get it.

RN: (...) try to do it while you walk [D generates the graph shown in Figure 5].

**Figure 5: D keeps the difference graph on zero while walking**

D: (...) You don't have to keep the remotes in (...) one position.

RN: Like, keeping [them] together?

D: keep them at the same level.

### Commentary

D came to create a difference graph with a clear plan: stay still with the two remotes next to each other. He had a well-defined sense that a dark blue graph on the horizontal axis “converted” into the two Wiimotes being equally distant from the sensor. Moreover, D easily showed in Figure 5 that that condition was indifferent to his walking distance from the sensor (“You don't have to keep the remotes in one position”). The point, he said, was to “keep them at the same level.” His choice of words (“same level”) reflects a phenomenon, we think, of great significance: “level” is customarily a term for height, which was relevant to the light blue and pink graphs being at the same height, but not necessarily to the Wiimotes that could be at different heights while keeping equal distances to the sensor. D articulated an instance of a type of semiotic sliding between qualities of the graph and qualities of the remotes, such that they could apply indistinctly to one or the other.

### Episode 3: Z works with the difference graph above and below the x-axis

In between Episodes 2 and 3 the children generated graphs to either keep the dark blue graph above or below the horizontal axis. Along that sequence, Z generated the graph shown in Figure 6.

**Figure 6: Z generates a graph in which the difference graphs goes above and below zero**

RN: So, how did you change [the dark blue line] from below to above?

Z: Em, by changing which controller was in front.

RN: So which one was in front here? [points to the dark blue graph around the 4<sup>th</sup> second]

Z: Em, [light] blue.

RN: (...) And do you have a sense for why for the blue, for the dark blue line, to be below [the x-axis] then the pink has to be below [the light blue graph]?

Z: Em, yep. Em, it's something to do with like maths and, like, because on there, it says the [likely pointing at the light blue one remote on the screen] has been taken away and then it's hard to tell because it's not actual numbers but if you have more on one side, that will be a negative number... then, then, if you have them on the other side, it'll be a positive number, which is that [points to the screen with the remote].

### Commentary

In this exchange Z describes qualitative differences of one kind (i.e. graphical configurations on the computer screen) and qualitative differences of another kind (i.e. bodily motions and postures) percolating onto each other. Sometimes these qualitative differences mutually communicate along critical points, such as the blue and pink Wiimotes being next to each other, as the condition that tips the cases of the minus graph being positive or negative. In other cases, the qualitative differences of each kind adopt corresponding ordinal arrangements along more or less, such as a Wiimote being closer or farther to the sensor bar matching its graph being higher or lower on the screen. Some of these qualitative differences can, in principle, be located on a metric scale, such as the distance between each remote and the sensor or the height of each graph at a given time. However, in this episode Z does not operate with metric scales. He said, for instance, “if you have *more on one side*, that will be a negative number” or “it’s not actual numbers.” Or he distinguished which remote is on front, rather than estimating distances between them. The focus of this commentary is to foreground ordinal arrangements of qualitative differences of unlike kinds, via critical points or corresponding alignments of more and less.

### Discussion

In the introduction we distinguished the attainment of abstraction along paths of white or black light. Whereas the mode of white light calls for navigating a *surplus* or overabundance of sensible qualities, the case of dark light is one of deficit of sensible qualities enabling zones of vagueness. In the episodes described above, the radical expansion of relevant sensible qualities encompasses the infinite nuances of kinesthesia. In our commentary for Episode 1, we described such kinesthetic expansion as a vivid broadening of the sensory qualities at play.

The introduction also stated the question of this study: What kind of navigation arrives at abstraction across a *surplus* of sensible qualities, of the white light type (in terms of generals)? Our commentary to Episode 2 suggested a type of semiotic sliding between qualities of the graph and qualities of the remotes, such that they could apply indistinctly to one or the other. Additionally, in the commentary to Episode 3 we considered the notion of qualitative differences of dissimilar kinds percolating onto each other, either via critical points cutting across them or mutual exchanges between corresponding ordinal arrangements of differences of degrees (i.e. more/less). All these processes amount to opening channels of flow and exchange among sensible qualities, such that

these cease to be self-enclosed and start to configure a plane of unity, which, far from denying their differences, brings them into mutual circulation and, therefore, speaks directly to navigating generals.

# Color-coding as a means to support flexibility in pattern generalization tasks

Per Nilsson<sup>1</sup> and Andreas Eckert<sup>2</sup>

<sup>1</sup>Örebro University, School of Science and Technology, Örebro, Sweden; [per.nilsson@oru.se](mailto:per.nilsson@oru.se)

<sup>2</sup> Örebro University, School of Science and Technology, Örebro, Sweden; [andreas.eckert@oru.se](mailto:andreas.eckert@oru.se)

*This study investigates how color-coding can support processes of flexibility in figural pattern generalization tasks. A lesson from a Grade 8 class serves the case for our investigation. The lesson is part of a larger research project, which is based on the iterative research methodology of design experiments and involves a total of six lessons, distributed over two classes (three lessons in each class). The study shows how coloring can encourage students to move from recursive strategies, like successive addition, and support processes of flexibility in linking algebraic expressions and the meaning of  $n$  to visual structures of an expanding figural pattern.*

*Keywords: Pattern generalization, visualization, color-coding, time-limitation, flexibility.*

## Introduction

In the development of algebraic thinking, students need to learn to see connections between the structure of a pattern and how the pattern can be described by a general algebraic expression (Rivera, 2010). It is crucial to discern a pattern unit when making such connections, around which a pattern structure can be modeled in relation to the place order of the elements in a pattern series (Nilsson & Juter, 2011).

Based on a constructivist methodology, educational research in mathematics has significantly contributed to our developing understanding of how students may obtain algebraic generalizations involving figural and numerical patterns. However, our knowledge is less extensive on how teaching can support the learning of pattern generalization (Rivera, 2010). In other words, if students need to learn to connect visual and symbolic elements effectively in relation to a structural unit, there is a need for further investigations on learning activities that can support that coordination to take place (Rivera, 2010). In this study we aim at making a contribution to such investigations by investigating how *color-coding* in task design (Watson & Ohtani, 2015) can support students' pattern flexibility in the visualization of structures in figural pattern generalizations (Figure 1). We address the research question: How can color-coding be implemented in task design to support flexibility in students' visual structure reasoning, in order to reach a general expression of a figural pattern?

## Theoretical background

Individuals see patterns differently depending on how they perceive the structure of the pattern and conceptualize pattern-units (Rivera, 2010). Investigating 8-13 year old students' generalization of linear pattern Stacey (1989) found that the constant difference property was largely recognized and used as a unit to find the  $n^{\text{th}}$  element by a recursive process of successive addition of this property. Stacey also found that some students were using proportional reasoning, according to the constant difference property. However, when adopting proportional reasoning, Stacey saw that students may

tend to ignore additive elements of a pattern; a significant number of students used a direct proportional method, determining the  $n^{\text{th}}$  element as the  $n^{\text{th}}$  multiple of the difference. For instance, the constant difference is three in Task 5 (Figure 1). Applying a direct proportional method of the  $n^{\text{th}}$  multiple of the difference results in the generalization  $3n$ , which excludes the extra dot that must be added.

Successive addition of the constant difference property is limited to linear patterns. To develop

**Task 5.** Miriam was thinking according to the picture. Pick the expression you believe best matches her picture.

**Figure 1: Color-coding in the expansion of a chair**

general expressions of patterns where the difference between subsequent elements in the pattern is not constant (e.g. quadratic patterns) one needs to adopt visual structure reasoning (cf. Rivera, 2010; Stacey, 1989). In Task 5, the constant difference is three and, applying the strategy of successive addition, the number of dots for the fourth figure is found from  $4 + 3 + 3 + 3$ . If we generalize this strategy we reach the expression  $3n + 1$ . However, in visual structure reasoning we define the unit by partitioning the figures in appropriate parts, in relation to the place order of the figures (El Mouhayar & Jurdak, 2015). In Task 5 we can visually structure the third figure in threes. In other words, the third figure of the pattern is composed by three threes plus one extra dot. Similarly we find out that the fourth figure of the pattern consists of three fours, plus one extra dot. Obviously we come to the same general expression,  $3n + 1$ , as in the additive situation. However, important to note is that  $n$  has a different meaning in the two situations. In successive addition  $n$  gains meaning as the number of constant differences, related to the place value of the  $n^{\text{th}}$  element in the series, whilst in visual structure reasoning  $n$  is a structural feature of a figure.

Generalization tasks are often grouped in near generalization tasks and far generalization tasks (El Mouhayar & Jurdak, 2015). Near generalization tasks involve finding the value of a step that is close to previous steps and far generalization tasks consist of determining the value of a step that is relatively far from given steps. Previous research reports that while near generalization tasks are accessible to a majority of the students, solving far generalization tasks is not. In the present study we will use both near and far generalization tasks, to challenge pattern flexibility, towards the formulation of a general expression, which is based on visual structure reasoning.

It has been observed that, once students have fixed on a pattern in a certain way, it can be hard for them to give up their perception (Lee, 1996). The key to success of seeing an algebraically recordable pattern seems to be at the first stage of pattern perception, where a certain flexibility is necessary to hit on a mathematically recordable pattern (Zazkis & Liljedahl, 2002). Visualizations

of a pattern can provide strong support for the symbolic representation of a pattern (Healy & Hoyles, 1999). Perception, or visualization, in pattern generalization is however not a passive process (Nilsson & Juter, 2011). Getting insight to a problem situation includes an operative, analytical activity (Deliyianni, Elia, Gagatsis, Monoyiou, & Panaoura, 2009; Duval, 1998), like structuring a figure into appropriate parts and/or transforming a figure into another figure (Rivera, 2010). In the present study we will investigate how a teacher can use color-coding as a visual means for supporting flexible, visual structure reasoning, to reach a general expression for a figural pattern.

## Method

### Design research methodology

This study is part of a larger research project that investigates teaching and learning of pattern generalization. The project follows the methodology of design experiments (Cobb, Confrey, Lehrer, & Schauble, 2003), involving a lesson series of three consecutive lessons. The project team consists of two researchers, the authors of the paper, and two teachers (Teacher A and Teacher B). Teacher A taught a class of 13-year old students and Teacher B taught a class of 14-year old students. All lessons were developed and analyzed according to *prospective*, *reflective* and *retrospective* analyzes (Cobb et al., 2003). Each lesson was conducted twice: First in Teacher A's class and then in Teacher B's class. The changes made to Teacher B's teaching were based on reflective analyses of what happened in the corresponding lesson of Teacher A's teaching. In the present study we focus exclusively on Lesson 1.

Lesson 1 involved seven tasks, distributed through Socrative<sup>1</sup>, and aimed to support flexibility in visual structure reasoning in pattern generalization. All tasks in Lesson 1 were situated in the task context of the growing chair-pattern (Figure 1) (Rivera, 2010). In Lesson 1, a time-limited far generalization task and color-coding were at the heart of the lesson. We focus, particularly, on Lesson 1B (Teacher B's class). However, the results of the study are based on a retrospective analysis of both Lesson 1A and Lesson 1B, and the relationship between them. All lessons were video-recorded from three different positions; one placed at back of the classroom, one at front of the classroom and one zooming in on a specific group.

The answers of each task were made available to both the teacher and the students, which were intended to reveal students' reasoning and create an opportunity for whole class discussion where students could react on each other's reasoning. No color-coding was added to the first four tasks. The first task was a near generalization task. Here the students were asked to figure out the number of dots in the 4<sup>th</sup> figure of the chair-pattern. The second task was a semi-far generalization task, where students were asked to figure out the number of dots in the 9<sup>th</sup> figure. The third task and follow up question were far generalization tasks about the number of dots in figure 1000. In the third task the students had a limited amount of time. They were asked to reflect on whether it was

---

<sup>1</sup> Socrative is an online student response system where teachers post questions that show up on students' devices and allows them to post answers. Answers become instantly available to the teacher, which s/he can choose to make available to the students.

possible for them to complete the task within a minute with the method they had been using in the second task. Until now the students were expected to reason according to the constant difference property, since that was how they had solved similar tasks in the past. Task four asked students about the meaning of  $n$  in pattern tasks. The task was supposed to challenge the students to start to reflect on how  $n$  can be connected to place order in a pattern. Figure 1 shows the fifth task, with a color-coded visual structure, designed to stimulate students' visual structure reasoning. The sixth and seventh task flipped task 5 around and asked the students to color-code different versions of algebraic expressions. First the students were asked to apply  $n+(n+1)+n$  on the seventh figure; then, in task seven, they color-coded for example  $(n+1)+(n-1)+(n+1)$ . The tasks, and their relationship, aimed at furthering the students' flexible reasoning; to be flexible in ways of discerning visual structure units by reversing and expanding their reasoning in task 5. To open up for whole class discussions, the students were asked to share their color-coding by publishing them in Padlet<sup>2</sup>.

### Method of analysis

The analysis aimed to investigate how color-coding can support flexibility in students' visual structure reasoning, in order to reach a general expression of a figural pattern.

The analysis followed in chronological order, according to the sequence of the seven tasks. In the first step, we coded and grouped the data according to the ways in which students distinguished and built their reasoning on a pattern unit and connected a pattern unit to  $n$ , to the place order of the figure in question. Next, we investigated how they changed their way of reasoning about the chair-pattern during the lesson. Particularly, we looked in detail at how color-coding supported students to move from the strategy of successive addition to discern a unit in the visual structure of a pattern, connected to  $n$ , i.e. to the place order of the figure in question.

### Result and analysis

#### Successive additive reasoning and $n$ as a symbol for place order of any figure in the pattern

In the first task, 75% of the students claimed that the fourth figure contained 13 dots. Many students discerned three as the constant difference property of the pattern and used this property in successive addition. In order to challenge successive addition and to prompt proportional reasoning the teacher introduced Task 2 and 3. In Task 2 the students were asked to determine the number of dots in the ninth figure. While the students were working on the task, the teacher walked around in the classroom and listened to the groups. He noted that most students conclude that the ninth figure contains 28 dots and that they reached this by successively adding up by three. In order to challenge successive additive reasoning, the students were asked figure out the number of dots in the 1000<sup>th</sup> figure within one minute, based on the strategy they used in Task 2. This task stimulated monitoring processes (Stylianou, 2002); it challenged the students to reflect on their strategies and how efficient they were. The students submitted their individual answers in Socrative and about 40% of the students believed that they could not determine the number of dots in figure number 1000 within one minute. Strategies that the student found too time-consuming were, for instance, to draw all

---

<sup>2</sup> Padlet is an online virtual pinboard that allows students to publish contributions that can be instantly available for the whole class on the white board or on students' own devices.

figures and count the dots or to successively add threes. The formula  $3n+1$  had not yet been expressed by the teacher or any student. But from students' group-work the teacher observed that some students expressed aspects of such reasoning. The teacher asked Charlie to explain:

Charlie: Because, as it [the pattern] constantly increases by three, you need to multiply thousand by three and then plus one.

Charlie gives further reasons for his strategy by showing how it works in an example where the number of dots of a figure is known to the class or can be visually confirmed:

Charlie: For instance, if we look at figure 3 [within Figure 1 above], it [the pattern] constantly increases by three, and we take three times three it will be nine and then, as it is ten [dots] there [pointing at the board], you need to add one more. And, then it is the same with the other; thousand multiplied by three plus one.

After the three first tasks we have reason to believe most students in the class came to understand that they can multiply the number of a given figure with three and then add one to reach the number of dots of any figure. However, a general algebraic expression involving  $n$  had not yet been formulated. In Task 4 the students were asked to post the meaning of  $n$  in Socrative. The most common posts were expressions of  $3n+1$  and that  $n$  stands for any figure. The teacher asked, "Do we agree, everyone who agrees raise their hands, that  $n$  stands for any figure?" Almost all students raised their hands. That the students had a sense of  $n$ , as a symbol that stands for any figure, was assumed to be necessary for moving on to Task 5. Task 5 introduced color-coding as a means for supporting students to discern a unit in the visual structure of a figure, in relation to the place order of the figure in question.

### **Supporting structural flexibility by color-coding**

The symbol  $n$  was now understood by most students in the class, as a symbol for place order of any figure in the pattern. However, up until now,  $n$  was seen as a variable, determining how many constant differences one should multiply to reach the number of dots in any figure. Tasks 5, 6 and 7 were designed to change perspective on  $n$ . The tasks were designed to stimulate students' pattern flexibility by pushing them to make sense of  $n$  in the visual structure of the expanding chair-pattern.

The students posted individual answers on Task 5 in Socrative. The results were rather even between alternative b) and c) (Figure 1). The students were then asked to discuss in their groups and to explain to each other how they were reasoning. After the group-discussion the students were asked to post an individual answer again and now the majority of students chose alternative b). George was asked to present his reasoning at the whiteboard:

George: I thought I would figure this out first [pointing to  $(n+1)$  in the expression]. First I was thinking  $n$  plus one. It is this [pointing to the two blue dots in the first figure of the pattern]. This is the blue, one could say.  $n$  plus one. And, both of them [pointing to the two red dots in the first figure] are  $n$ .

According to flexible processes, George then said that alternative c), displaying  $n+1+n+n$ , is the same as alternative b). The only difference is the order of the signs. He implicitly manipulated the expression by visualizing a bracket in the expression  $(n+1)+n+n$ .

A number of students answered a), displaying  $2 \cdot n + n + n$ . The teacher asked why alternative a) was chosen. Charlie responded:

Charlie: It works for the first figure but not for the other.

We believe this is a relevant interpretation made by Charlie and, supported by his observation, we also suggest that deciding on alternative a) is based on calculations rather than on visual structural reasoning like the one George showed an example of. The color-coding implemented in the design of Task 5 helped George to externalize and show in public his way of reasoning. The design supported George to make sense of  $n$  in the visual structure of the pattern and to communicate his meaning making to the class by visually linking parts of the expression to the corresponding parts of the figure.

The class turned to Task 6, to color the seventh figure of the pattern according to  $n + (n+1) + n$ . In Task 5 the class observed and followed how George linked an algebraic expression to the color-structure of the pattern figures. Task 6 aimed at letting students make sense of and generalize this idea according to a new figure. The students worked in pairs. As they finished, they posted and made their solutions public at the whiteboard. The group-solutions witnessed the fact that several students had changed perspective of the meaning of  $n$ , to see  $n$  in the structure of the figures. The teacher picked out Rikki's solution to Task 6, where the link between the algebraic expression and the coloring was evident and proper according to the task (Figure 2).

Figure 2: Rikki's color-solution to Task 6

Figure 3: Rikki's color-solution to Task 7

Rikki: First I was taking  $n+1$  [saying something audible] and, then I draw that in the middle [The teacher points to the vertical line of eight dots that Rikki has colored in blue].  $n$  is the number of the figure, thus seven [the teacher is nodding in confirmation]. But then it was plus one so, then I did eight. And then it was  $n$  on the other sides. Seven down and seven up [the teacher moves his hand over the picture to illustrate down and up of the seven dots Rikki is referring to].

In Task 7 the students were working in pairs and used Paint to color other expressions in the pattern. The teacher noted that Rikki solved the first subtask of Task 7, coloring  $(n+1) + (n-1) + (n+1)$ . For some reason the teacher did not succeed in presenting Rikki's own solution on the board. Instead, he showed an uncolored picture of the three first figures of the pattern and asked Rikki to guide him through the coloring of  $(n+1) + (n-1) + (n+1)$  in the second figure of the pattern (Figure 3). That the teacher failed in up-loading Rikki's solution became something positive from a teaching

perspective. Now Rikki was forced to give details of her reasoning so the teacher was able to understand how he should color the figure. Moreover, in the dialogue between the teacher and Rikki, the rest of the class was provided an opportunity to follow, in detail, how the solution was constructed.

## Concluding discussion

In this paper we addressed the research question: How can color-coding be implemented in task design to support flexibility in students' visual structure reasoning, in order to reach a general expression of a figural pattern? In answering the research question, we have shown how coloring in pattern generalization can stimulate processes of flexibility (Stacey, 1989) in linking algebraic expressions and, particularly, the meaning of  $n$  to visual structures of expanding figural patterns.

The present study sheds new light on task-design to support reflection on visual structures (Rivera, 2010) and pattern flexibility (Nilsson & Juter, 2011). In pattern generalization, the first stage of pattern perception is crucial, where a certain flexibility is necessary to hit on a mathematically recordable pattern (Zazkis & Liljedahl, 2002). To move beyond linear pattern generalizations one needs to discern a unit from the visual structure of a pattern, connected to the place order of the pattern-figures (El Mouhayar & Jurdak, 2015). The present study shows how color-coding can support such processes of flexibility by turning students' attention to the relationship between an algebraic expression and visual structures of the pattern. The color-coding prompted the students to change perspective of  $n$ , from a number variable (how many threes to multiply) to a visual unit in the structure of a figure. In particular, the analysis shows how implementing coloring in pattern generalization task, supported students in discerning and making sense of  $n$  in the relationship between  $n$  in the structure of a general expression and  $n$  in the structure of a figure.

The role of far generalization tasks, and the added condition of time-limitation, has not been the main focus in the present study because of limited empirical evidence. However, the analysis indicates that it might be worth re-considering the role of far generalization tasks in the learning of pattern generalization. Previously, research has focused on students' difficulties to account for far generalization tasks and how students find them more difficult than near generalization tasks (El Mouhayar & Jurdak, 2015). Near generalization tasks can be handled by recursive reasoning, which is not as applicable to far generalization tasks. Recursive reasoning necessitates that the preceding value of the pattern is known. So, to determine the value of the 1000<sup>th</sup> figure, one needs to know the value of figure number 999. The present study also shows that students find a far generalizing task more difficult than near generalization task due to recursive reasoning, coming in the form of successive addition. Challenging students to a far-generalization task did not support multiplicative, proportional, reasoning in a direct sense. However, the analysis shows how it made students reflect on and examine limitations of a recursive, additive approach and come to be responsive to proportional reasoning. Hence, instead of just accounted for students' difficulties, the far generalization task provided the teacher a context for exposing the limitation of successive additive reasoning and for highlighting and emphasizing multiplicative structures. In the present study the teacher created such a context by making Charlie's reasoning in Task 2 public.

The outcome of the present study calls for further research in the realm of task and lesson design (Watson & Ohtani, 2015). Still many questions are open on a patterning approach to algebra. We need to know more about tasks that challenge students' flexible reasoning and engage students in visual structure reasoning. We encourage research to further explore coloring as principles for

designing tasks in authentic practices of algebra teaching. The current study also indicates the need to carefully sequence tasks in pattern activities, in order to encourage processes of reflection and flexibility that move students' understanding towards multiplicative, structural, reasoning, which can be used to handle patterns that go beyond linear patterns.

## A classification scheme for variables

Reinhard Oldenburg

University of Augsburg, Germany; [reinhard.oldenburg@math.uni-augsburg.de](mailto:reinhard.oldenburg@math.uni-augsburg.de)

*This theoretical paper presents a framework for the classification of variables (as used in school) that goes beyond traditional classifications by clustering variables according to their syntactical, semantical and pragmatical properties. Moreover, the paper associates certain emotional qualities to these aspects of variables and indicated how they help in understanding students' misconceptions.*

*Keywords: Variable, semantics, classification.*

### Introduction

Several variable classifications have been proposed. Küchemann (1979) has distinguished empirically several ways to use letters. The question what these letters are from an ontological point of view is not in the focus. Usiskin (1988) describes four conceptions of algebra and the use of variables in each conception. The discussion of what a variable is and how it is used is mixed up. In the German speaking countries, the work of Malle (1993) has been influential who defined three aspects of variables: Variables as placeholders, as calculus elements and as objects. Ely & Adams (2012) describe three usages of variables: unknown, placeholder, variable. Other topics of interest have been the ability to see structure and connections to computer science (Arcavi 1994; Heck 2001). A common defect of these approaches is that there is no clear distinction between the question of what a variable is and how it is used. Moreover, a perspective on the concept development is missing.

### Linguistic as a basis

Starting with C. W. Morris (1938) linguistics distinguishes three aspects of language: syntax, semantics and pragmatics. Syntax comprises the formal rules that govern how signs are arranged and treated. Semantics deals with the references to objects and clarifies what is meant by syntactically well-formed expressions. Pragmatics is about the use of language that is adequate in certain situations.

The syntax of languages can be described by grammars. But knowing the syntax of algebra is neither sufficient nor fully necessary to be successful in algebra (Hodgen, Küchemann & Oldenburg, 2011).

Understanding the semantics is the next building block. Semantics is about the interpretation of signs, especially it clarifies how signs refer to objects (cf. Honderich, 1995, p. 820). In algebra inadequate semantic ideas held by students are e.g. that variables stand for real world objects or that different occurrences of the same variable can stand for different objects.

The last aspect is that of pragmatics. In linguistics this is a somewhat fuzzy concept. In (Honderich, 1995) the following definition is given: "The study of language which focuses attention on the user and the context of the language use rather than on reference, truth or grammar." Levinson (2013) discusses several possible definitions, e.g. "Pragmatics is the study of those relations between language and context that are ... encoded in the structure of the language."; that is, the language reaches out in a sense to link with the situation. This high-lights the importance of context!

These three aspects of language will now be used to analyze different notions in turn.

## Detailed analysis of the concept of variable

While a lot has been written about variables, it is not that clear what questions are answered. From the perspective of language levels one may ask three questions about variables (here variables is used in a wide sense, including all symbolic uses of letters, not just varying quantities):

- What do variables look like? (syntax)
- What do they mean, i.e. what are they and how are they related to other entities? (semantics)
- How (and to what end) are variables used? (pragmatics)

From this perspective, one sees that the various authors answer different questions. Küchemann (1979) describes how letters are *used*, but nevertheless his classification is not purely pragmatical but also semantical. Malle (1993) uses the word “aspect” and claims that all variables can be seen under each of his three aspects. This suggests that he discusses different pragmatical ways of variable use too, but in fact his aspects (placeholder, object, symbol) are semantical in nature. Heck (2001) states that variables can hardly be defined because there are so many different uses of them. Among the semantical considerations in the literature, many are somewhat unclear. One example is the conception that a variable represents a set of numbers simultaneously (Malle, 1993). As I shall show, this is at odds with sound logical semantics of variables. Summarizing, it seems that most authors give diverse answers to the question what variables are, even on the semantical level. In this paper I start from scratch and give an exposition that covers, I hope, all relevant aspects on all levels.

### The syntax of variables

Little is to be said about the syntactical aspect of variable: In most cases, they are letters, on others they are compound symbols such as  $x_1, x_i, f(x)$ . (Syntax of expressions is richer, of course.)

### The semantics of variables

What are variables? I have partially answered this question in (Oldenburg, 2015) and will build upon this in this paper. It turns out that there are two questions that distinguish different kinds of variables:

1. Is the variable a part of language used to talk about mathematical objects, or is it a mathematical object itself?
2. How is the variable linked to its value? Is it a container for or a reference to something?

Here “something” is typically a number or other mathematical object (e.g. vectors, functions, points).

Now, from the two 2-fold distinctions a table can be presented:

Variable is...	Container C	Reference R
An object in its own right: OLA	Placeholder that may contain a number or something: OLA-C	A symbolic object with properties like domain, current value etc.: OLA-R
An element of the language used to speak about objects: LLA	A gap in a sentence to fill in the name of a number or something: LLA-C	A symbol without properties, its only function is to refer: LLA-R

**Table 1: Four semantical kinds of variables. (OLA=Object Level Alg., LLA=Language Level Alg.)**

Before looking in more detail on this four kinds of variables, I state the hypothesis that there are no more kinds necessary. Especially, concepts like parameters or unknowns are best distinguished on the pragmatic level as will be explained in the next section.

The distinction in this table separates kinds of variables by ontology: They are different not only in their usage but in their being, as I shall show. Yet, all these four kinds are variables in the sense that variables used in mathematics books can be classified into this table and all cells are non-empty.

The upper row (variables as objects) will be called object level algebra (OLA) and the lower row language level algebra (LLA). With this distinction I build on the one of (Oldenburg 2015) but using a somewhat adapted terminology. Moreover, the columns are abbreviated by an appendix C (container) or R (reference) so that the four cells are OLA-C, OLA-R, LLA-C, LLA-R.

OLA-C: Given the equation  $5 + \square = 8$  one inserts 3 into the placeholder to get  $5 + \boxed{3} = 8$ . Here the placeholder contains the number, and it is a real object. It still exists after insertion of the number and one may move it around, e.g. to get  $\boxed{3} + 5 = 8$ . One could operate on these objects, e.g. by drawing different kinds of boxes and moving them as in  $\square + \square = \square + \square$  .. This kind of variables are sometimes introduced by textbooks using ten metaphor that the variable is a match box (an object) that contains a certain number of matches – the variable's value.

LLA-C: Given the equation  $5 + \square = 8$  one replaces the placeholder to get  $5 + 3 = 8$ . Here the placeholder was only a language element, a marker of a spot to complete an expression.

LLA-R: Variables are like flexible names, they name some objects, but are not objects themselves. A typical example is given in Fig. 1: Variables there are letters that refer to certain values - they have no further properties, they are just names that link to (i.e. refer to) a value.

2 Übertrage die Tabellen ins Heft. Setze für z sowie a, b und c die angegebenen Zahlen ein. Vergleiche die Ergebnisse in den Spalten.

3	4	5	17		
4	5	6			

**Figure 1: LLA-R use in a German grade 5 school book (Formel 5, Buchner Verlag)**

OLA-R: Consider the idea of variation with typical questions such as “how do  $x$  and  $y$  change together?” If  $x, y$  were just (not yet fixed) names for numbers in the sense of LLA-R, then one could substitute them with their referents, but it would be senseless to ask e.g. “how do 5 and 9 change together?”. Hence, these are objects of thought with their own properties. The same holds true in sentences like “ $x$  increases”.

This distinction solves question 1 from above: In case of LLA, the set  $\{x, y\}$  (over  $\mathbb{R}$ ) has one or two elements (numbers), depending on  $x = y$ , in OLA it has two elements, namely two variables (that may have the same value).

Note that the standard view of mathematical logic – basically coined by Tarski, see (Tourelakis, 2003) – is that of LLA-R<sup>1</sup>. In modern logic, variables are syntactical elements of the language of logic. The semantics is defined in terms of interpretations which link each variable to an object it refers to. It should be noted that every horizontal row of Figure 1 gives an interpretation for the variables of the expression so that this seemingly abstract concept from logic is very graspable for students.

LLA variables are used in most programming languages (C, Java<sup>2</sup>, Python, Prolog). Most variables are of reference types, but not all.<sup>3</sup> That most programming languages don't use OLA follows from the simple fact, that the symbols (the variable names) are usually not contained in the compiled binaries and that they cannot be stored in data structures (only their values can). In contrast, the languages of computer algebra systems usually allow variables to be stored in lists and sets and so they are (first class, in computer slang) objects and hence OLA variables. This argument is technical, but it shows several important things: First, the distinction can be clearly applied in this area. Second, it lies not in the eye of the observer what kind a variable is, it is not a question of how the variable is used or viewed, but it depends on the way semantics is realized by the language. Third, taking into account the details given in the footnote one sees that all four kinds are realized in languages.

A tricky point comes from the fact one may have LLA-variables that refer to OLA-variables. This is the case e.g. when one considers polynomial rings: In a formula like  $p = 2x^2 - 1 \in \mathbb{Z}[x]$  the  $p$  is a language reference LLA-R while  $x$  is an object in the sense of OLA, because the domain of objects is  $\mathbb{Z}[x]$ . Note that the variable  $x$  of  $\mathbb{Z}[x]$  cannot be LLA, because it can be assigned as a value to other variables. Moreover,  $x^2 + x \in \mathbb{Z}_2[x]$  cannot be build up from a LLA variable, because for all objects from  $\mathbb{Z}_2$  that  $x$  may refer to or stand for or contain, the value is 0:  $1^2 + 1 = 0, 0^2 + 0 = 0$ . Thus, if  $x$  was just a language element that refers to some element of  $\mathbb{Z}_2$  then this polynomial would be just 0.

While for logic that deals with established math LLA-R (where some special domains like the polynomials may contain OLA-R variables) is sufficient, I suppose that in the process of developing mathematics the upper row is important as well and I suppose that learners initially have least problems with OLA-C (match box metaphor). This is also supported by the following empirical observation: When asking students, teachers and mathematicians what they see in their mind after inserting the solution into  $5 + \square = 8$ , most students say 'three in the box', teachers are undecided and most mathematicians opt for 'three without box' – supporting that this is a question of expertise level.

---

1 There has been some discussion about LLA-C as an alternative to LLA-R for variables in first order logic, see (Quine, 1974) for a thoughtful discussion which finally rejected LLA-C. This discussion is interesting from an educational point of view, but I have to skip it due to limited space.

2 In Java, a statement like `int n=1;` clearly defines a LLA-R variable. However, there is a subtle trick to have a kind of OLA-C variable: `Integer m= new Integer(5);` defines a LLA-R variable  $m$  which refers to an unnamed object which is in fact a OLA-C variable, namely a container for a value.

3 For example in the C programming language one may define the maximum of two numbers either by a function `int max(int a, int b) {return a>b?a:b}` or by a macro `#define max(a,b) {a>b?a:b}`. In the first version  $a$  and  $b$  are LLA-R, in the second LLA-C variables.

One should note that these different kinds of variables are present in the literature, but it seems that they are mixed up with the use of variables (which I will deal with in the next section) and on the other hand, often authors claim that one view is the correct one, while the claim of this paper is that these are different kinds of variables. Container types being typical for young learners while the reference types are more common among educated mathematicians. Within the reference types the two kinds of variables (OLA-R, LLA-R) is changing according to the development status of the theory. The object variables are more typical for math in the phase of development, while the language view is typical, when the domain of objects is completely understood and well-constructed.

This subsection closes with some quotes that illustrate how different researchers' positions can be located within the theoretical framework outlined above. Bardini et al. (2005) take the view that variables are objects (in the sense of OLA-R): "In the generalization of patterns, letters such as 'x' or 'n' appear as designating particular objects - namely, variables. A variable is not a number in the arithmetic sense. [...] A variable is an algebraic object.". Moreover, they distinguish different kinds of these objects: "Yet, the algebraic object 'variable' should not be confounded with another algebraic object -the 'unknown'". For Linchevski (2001), on the other hand, variables are transparent language elements in the sense of LLA, not objects in their own right: "Operating on and with the unknown implies understanding that the letter is a number. It does not only symbolize a number, stand for a number, and it does not only tag/label/sign for an unknown number." (p. 143). Epp (2005, p. 54) states: "variables are best understood as placeholders", which follows the standard mathematical logic but may be problematic in educational contexts. Summing up, there is no consensus of what variables are, but I claim that the four types constitute a sound basis for didactical research.

### **The pragmatics of variables**

What most publications on variables discuss, is not what variables are (the semantics), but how variables are used, in what context and for what purposes, i.e. the pragmatics of variables.

A pragmatical distinction from the logic literature that plays only a modest role in educational texts is that between bound and free variables. The point here is simply that the quantification does not alter the variable. The variable itself has the same semantics, regardless of it being free or bound.

There is, however, still a lot to say about the pragmatics of variables. Let's first make a detour into research on computer science education. Sajaniemi (2002) has introduced the notion of a "role of a variable" in (procedural) programming languages. He identified (by analyzing code written by a large number of programmers) several roles, e.g. fixed value (constant), stepper (stepping through a succession of values), follower (a variable that always gets its new value from the value of another variable), most-wanted holder (a variable holding the best value encountered so far). All these roles can be taken by the very same variables of a programming language. The variables' semantics is fixed by the language – the difference here is thus not on semantics but on the pragmatical level. Sajaniemi found that explicitly teaching these roles to novice programmers boosts their learning process. It seems likely that the same may be achieved in mathematics education.

So, what could be variable roles in elementary algebra? The literature gives many hints on this and without tracing back every role to the various studies that have dealt with it, I'll simply present:

- Variable used as a fixed number:  $r=5$ ,  $\pi=3,141\dots$ , often such variables are called constants or parameters, depending on the extent to which one expects their reference to be changed.
- Unknown. A number (or more general object) that is (not yet) known
  - It may be a number to be detected (e.g. as the solution of an equation – non-uniqueness causing some troubles eventually).
  - It may be a reference used to argue about it (“tentative number”), e.g. the length of some segment in a construction.
- General number: A reference to or container for many possible values. This can be:
  - an open form (e.g. an odd number  $2n + 1$ ,  $n \in \mathbb{N}_0$ ).
  - a changing quantity (e.g. the value of an observable (like time, charge, money,...)).

It is a nice exercise to go through all these uses and imagine how they can be realized on the semantical bases of each of the four types of variables.

### Some more issues

Working successfully on problems requires competences on all three aspects. To illustrate this, I take the example to choose between two car rental offerings with ingredients like base price and a price per driven kilometer. On a pragmatical level one asks: What is the adequate mathematical tool? Table, graph, equation, inequation? Let's choose the latter. Then to semantics: Reference to relevant quantities are to be fixed: Let  $n$  be the number of kilometers to be driven. Then the prices of the two offerings are linear expressions in  $n$  and the condition that the first offering is better is e.g.  $50 + 1.5n < 30 + 2n$ . Now it comes to syntax (transformation according to rules). At the end one goes back to semantics (the meaning is to be clarified) and pragmatics (is it useful after all?).

The structure of this is displayed in the following table.

Phase	1	2	3	4	5	6
<b>Aspect</b>						
Situation	Problem					
Pragmatics		Choice of math				Application
Semantics			Fix references		Interpretation	
Syntax				Work formally		

**Table 2: Phases of mathematical problem solving**

In each phase the higher aspects guide work on the lower ones. The situation guides the pragmatical decisions and they in turn the semantical decisions. Finally, syntactical work is guided by semantics.

There is a certain analogy with the modelling circle of (Blum & Leiss 2005). This is not by accident: Modelling is essentially a translation process and hence language aspects come into play. Setting up the real world model requires pragmatic arguments, setting up the mathematical model is a semantical activity. Working inside a formalism is syntactical. When going back to real world, semantical issues come in again and in validation one has to deal with pragmatical issues.

One may object that assigning the labels syntax/semantics/pragmatics to the modelling circle does not give new insights but just groups together phases that are labeled by more specific concepts from the modelling theory such as mathematicising and validation. However, combined with the table above one may get a deeper understanding of the control flow inside modelling processes.

## Emotional dimensions

The theory of somatic markers (Damasio, 1996) assigns emotions the task to guide decisions. The word „decision“ has been used in the presentation above several times. This is not by accident. Doing math means taking a lot of decisions, e.g.: Table or Graph? Introduce one or two variables? Factorize or expand? To decide quickly on such cognitive questions emotions are important. Teacher experience is that students hold strong feelings for certain mathematical objects or situations. Research on emotions and math is mostly devoted to negative emotions (fear) and not specific to mathematical objects itself (cf. discussion in Trezise & Reeve (2014)). Trezise and Reeve view this as a shortcoming and they investigate emotional influence on doing algebra, not the direct connection between mathematics and emotions. However it seems plausible that there are emotions (in the generalized sense of (Silvia, 2009)) aligned with specific mathematics. I suggest:

Aspect	Emotion(al source)	Examples of situations with positive (p) and negative (n) emotions
Pragmatics	Utility	p: full decision tree, that handles all cases gives satisfaction n: Table that misses some obvious cases
Semantics	Logical soundness, clarity	p: successful check n: paradoxes
Syntax	Beauty, well-formedness, conformity	n: $3(4+)$ looks ‚broken‘ p: $1+x+x^2+x^3$ looks well ordered

**Table 3: Language aspects and emotions**

While this table cannot discuss the issue completely (e.g. neglects individual differences) I suppose that the role of emotions in guiding algebraic actions might provide a deeper understanding of algebraic thinking. Research mathematicians use the words beautiful/ugly very often. Related is the notion of algebra sense (e.g. Arcavi, 1994) that may have an emotional basis too.

## More algebraic examples

Here I show that linguistic levels are useful in interpreting students' errors. Consider the task to set up and solve an equation for this situation: "There are 84 balls of two colors and there are 10 more red than blue." It was found that even university level teacher students had problems of 3 categories: 1<sup>st</sup>: Pragmatic difficulties: Use of function (e.g.  $f(r, b) = r + b + 10$ ) or other in-adequate math. 2<sup>nd</sup>: Semantic difficulties: Many students worked with unclear references, e.g.  $r + (r + 10) = 84$ . 3<sup>rd</sup>: Syntactic difficulties: E.g. from the correct system  $b + r = 84, r = 10 + b$  one student concluded  $r = b - 84$  and thus  $b - 84 = 10 + b$  which, surprisingly, turned out to have no solution.

## Transforming equations equivalently? – theoretical considerations of equivalent transformations of equations

Norbert Oleksik

University of Würzburg, Germany; [oleksik@dmuwr.de](mailto:oleksik@dmuwr.de)

*Although algebraic transformations of equations are commonly used to identify solutions of equations, it remains unclear, which transformations are explicitly considered to be equivalent transformations, and which are not. Therefore, equivalent transformations of equations are analyzed, by using the notions of concept image, concept definition, aspect, and Grundvorstellungen, as well as their relations to each other. Different formal concept definitions of equivalent transformations of equations are examined to get a first impression of possible characteristics of concept images. As a further approach, Grundvorstellungen are derived from aspects of the equivalence of equations and put in relation to the theory of concept images. Different contradictions can be identified using these notions, which are possible sources of misconceptions.*

*Keywords: Grundvorstellungen, aspects, mathematical concepts, mathematics education.*

### Equivalent transformations of equations

Learners of mathematics are being introduced to equations in primary school. Simple arithmetic equations are to be solved by adding, subtracting, multiplying, and dividing numbers. In secondary schools, with the shift from arithmetic to algebra, variables are expressed by the use of letters. This is usually when pupils are introduced to more formal techniques of solving equations. They are transformed to other equivalent equations, so that a formula can be applied, or the solution is apparent (as in the case of the equation  $x = 3$ ). Since equivalent transformations of equations are a central tool for solving equations, the concept of equivalent transformations of equations should be well defined and known to every mathematician and teacher of mathematics. When considering the following two equations, the question whether the initial equation was transformed equivalently provides room for discussion:

$$x^2 = 4 \quad (x \in \mathbb{R})$$

$$x^4 = 16 \quad (x \in \mathbb{R})$$

Squaring the expressions of an equation is usually not considered to be an equivalent transformation of an equation (e.g. Vollrath & Weigand, 2007, p. 214), although it may lead to an equivalent equation, as in the example above. In order to analyze why some transformations are considered to be equivalent transformations, while others are not, even though they share the feature of leading to an equivalent situation, the theory of concept image and concept definition by Tall and Vinner (1981) is used. This theory will then be related to Grundvorstellungen, which has a long tradition in Germany, due to the works of vom Hofe (2016), using a model provided by Greefrath, Oldenburg, Siller, Ulm, and Weigand (2016), which offers a further approach to the concept image. Subsequently the geometric model for teaching transformations of equations as described by Filloy, Puig, and Rojano (2008) is being discussed in regard to the following theoretical considerations.

## Concept image and concept definition

An individual's view on a mathematical idea is not only shaped by the subject matter itself but also by further experiences. Therefore, Tall and Vinner (1981) differentiate between mathematical concepts and cognitive processes which resemble an individual's understanding of the concept. For the latter the term *concept image* is used "to describe the total cognitive structure that is associated with the concept" (Tall & Vinner, 1981, p. 152). When looking at the two equations above one may associate functions, variables, or something else with them. Given that within literature squaring is not considered to be an equivalent transformation of equations, it seems rather unlikely that the concept of equivalent transformation of equations is associated with the two equations above. It may even be declined to consider this as an equivalent transformation. Which leads to the assumption that the individuals concept image of equivalent transformations does not contain the operation of squaring. The question that naturally raises, from this little theoretical discourse, is how equivalent transformations of equations are defined. For this matter the term *concept definition* is used, which is "a form of words used to specify that concept" (Tall & Vinner, 1981, p. 152). A concept definition of an individual is referred to as *personal concept definition* and is not necessarily correct or existent (Tall & Vinner, 1981, p. 152). In contrast to the possibly erroneous personal concept definition, the formal concept definition is "accepted by the mathematical community at large" (Tall & Vinner, 1981, p. 152). It should be mentioned, that one can be able to state a "correct formal concept definition whilst having an inappropriate concept image" (Tall & Vinner, 1981, p. 153). It is the concept image that gives meaning to the concept definition (Greefrath et al., 2016, p. 103), while the definition may be just a memorized sequence of words. Prior to planning an empirical investigation of individual concept images and personal concept definitions of the concept of equivalent transformations of equations, it seems wise to examine the concept of these transformations theoretically by comparing different formal concept definitions.

## Formal concept definitions of equivalent transformations of equations

Equivalent transformations of equations can be defined as transformations which do not alter the solution set (Vollrath & Weigand, 2007, p. 242). In this definition no further information is given about the characteristics of a transformation. The key is the property of not losing or adding any solutions of (or to) the equation, which is crucial when it comes to solving equations. This would lead to the conclusion that the example above is an equivalent transformation of equations.

Walz (2017, p. 361) defines equivalent transformations of equations in contrast to transformations which *possibly* alter the solution set, which justifies the claim of squaring not being an equivalent transformation. When taking this condition into account, which is rarely made explicit, there are only few types of transformations left to be considered as equivalent transformations of equations. Adding (and subtracting) numbers, as well as multiplying (and dividing by) numbers other than zero always, lead to equivalent equations (Langemann & Sommer, 2018, p. 172). This demand for generality of not altering the solution set can only partially be granted when it comes to adding or multiplying expressions containing variables. One might accidentally divide by zero and lose one or more solutions:

$$x^2 = x$$

$$x = 1$$

Another definition highlights the reversibility of the transformation and states that transformations, which can be reversed, without changing the meaning are equivalent transformations (Langemann & Sommer, 2018, p. 172). Since it is not explicitly stated what meaning refers to in this context, this definition appears rather doubtful. Considering that an equation containing variables determines a set of elements for which it becomes a true statement (Kirsch, 1987, p. 106), it can be assumed, that meaning refers to the solution set as well. Drouhard and Teppo (2004) translate the German term “Bedeutung” (with respect to Frege), as denotation (instead of meaning as done in the translation above) as a subdomain of meaning and refers also to the truthfulness of equations (pp. 232–234). Therefore, it can be assumed that this is the case in this definition. None the less it is interesting in the manner that it highlights reversibility as a property of equivalent transformations.

When comparing these different definitions, it appears crucial, that the solution set does not change when an equivalent transformation is applied. This is the defining property of an equivalent transformation, in the first definition discussed. The second one extends it by demanding a certain generality and claiming it never alters the solution set. Although the third definition is not quite clear, it highlights another characteristic: equivalent transformations have to be reversible. It is noteworthy, that all of these definitions relate, more or less explicitly, to the solution set.

### **Aspects and Grundvorstellungen an additional approach to the concept image**

Given that (formal) concept definitions are the basis of concept definitions (Greefrath et al., 2016, p. 103) predictions about possible individual concept images can be derived from them. In order to draw further conclusions of possible characteristics of concept images the construct is approached by using the idea of *Grundvorstellungen* (GV) as an addition to the concept definition, which may also be part of a concept image (Greefrath et al., 2016, p. 103). Greefrath et al. (2016, p. 101) defined the term in the following manner: “A *Grundvorstellung* of a mathematical concept is a conceptual interpretation that gives it meaning” (for a more detailed discussion, see vom Hofe & Blum, 2016). Unlike the concept image, a GV relates to aspects of mathematical concepts (Greefrath et al., 2016, p. 101), while the concept image describes the whole cognitive structure that is associated with a mathematical context. The term *aspect* of a mathematical concept is defined as “a subdomain of the concept that can be used to characterize it on the basis of mathematical content” (Greefrath et al., 2016, p. 101). Because of these relations, identifying and examining aspects of equivalent transformations of equations offers new insights into possible characteristics of a concept image. Since the equivalence of equations appears to be the defining property of the equivalent transformations of equations and therefore characterizes it, it will be examined in greater detail in the following section.

### **Aspects of equivalence of equations**

Equivalence of two equations means that they share the same solution set (Kirsch, 1987, p. 108). Another possibility to determine the equivalence of two equations is by transforming one equation into the other using valid transformations (Oldenburg, 2016, p. 11). Since this takes into account transformational activities, the focus will be on this aspect of equivalence, which from here on will be referred to as *transformational equivalence*. This aspect of equivalence requires defining valid transformations. For this matter, two similar but different types of rule sets are described in the following.

## Balance rules

One type of rulesets for transforming equations are the balancing rules, which are expressed in regard to expressions (Malle, 1993, p. 219):

$$\begin{aligned} A = B &\Leftrightarrow A + C = B + C & A = B &\Leftrightarrow A - C = B - C \\ A = B &\Leftrightarrow A \cdot C = B \cdot C \quad (C \neq 0) & A = B &\Leftrightarrow \frac{A}{C} = \frac{B}{C} \quad (C \neq 0) \end{aligned}$$

The main feature of this ruleset is, that the two expressions on each side of the equal sign is being modified in the same way. The procedure is often visualized, by using scales, which stay in balance when the same amount of weight is added to or withdrawn from both sides. This is the reason why Malle (1993, pp. 220–221) refers to them as balancing rules. It should be noted though, that these rules can be visualized in various other ways as well.

## Elementary transformation rules

Another set of rules are the elementary transformation rules, which are again expressed in regard to expressions (Malle, 1993, p. 219):

$$\begin{aligned} A + B = C &\Leftrightarrow A = C - B & A - B = C &\Leftrightarrow A = C + B \\ A \cdot B = C &\Leftrightarrow A = \frac{C}{B} \quad (B \neq 0) & \frac{A}{B} = C &\Leftrightarrow A = C \cdot B \quad (B \neq 0) \end{aligned}$$

These rules may appear very similar to the balancing rules but require three expressions to perform a transformation of an equation. The given expressions of an equation therefore determine what kind of transformations can be performed. This may be seen as an advantage for choosing this ruleset over the balancing rules when teaching (Malle, 1993).

In contrast to the elementary transformation rules, the balancing rules allow working with additional expressions, while the elementary transformation rules only allow using the given expressions. The latter may be considered as special kinds of balancing rules, which require fewer calculations (Malle, 1993) as can be seen in the following example:

$x + 1 = 5$	$x + 1 = 5$
$(x + 1) - 1 = 5 - 1$	$x = 5 - 1$
$x = 4$	$x = 4$

## Grundvorstellungen and aspects of equivalent transformations of equations

An aspect is the basis of an individual GV, while at the same time the GV gives the subject meaning to the aspect (Figure 1). When applying this idea to equivalent transformations of equations, two different GVs can be derived, from the aspects described previously (Figure 1). It should be noted, that any GV that is derived from the balance rules can also be derived from the elementary transformation rules, given that they can be considered a shorter version of the balancing rules, which cover only certain cases.

**Figure 1: Relations between aspects and GV's (extracted from Greefrath et al., 2016, p. 103) applied to equivalent transformations of equations**

### Transposing GV

Using elementary transformation rules, the transformation may be perceived as a *transposition* of the expression according to the “change side – change sign rule” (Kieran, 1992, p. 400). This means that you exchange the operator in front of an expression with the inverse operation, while moving the expression to the other side of the equation. This idea of transposition appears to be coherent with the findings of Henz, Oldenburg, and Schöllhorn (2015), in which their hypotheses, that algebraic manipulations take place in an algebraic symbol space (and is linked to movement) is empirically supported. The scheme of this rule can be represented in the following manner (Malle, 1993, p. 218):

$$\frac{\blacksquare}{\blacksquare} = \blacksquare \Leftrightarrow \blacksquare = \blacksquare \cdot \blacksquare$$

### Balancing GV

The balance rules may be interpreted as “*doing the same thing on both sides*”. This can be represented visually by a scale that keeps the balance or as a more abstract scheme:  $A = B \Leftrightarrow A \circ C = B \circ C$ . Overly generalizing a scheme, may lead to errors in performance (Malle, 1993, pp. 172–175). In this case it may lead to the misconception, that squaring two expressions of an equation always leads to an equivalent equation. This demonstrates how problematic generalizations of a scheme may be, if no further knowledge is being acquired about when it is appropriate to apply a certain rule.

### Example: geometric model and GV's

So far models for teaching equivalent transformations of equations have only been mentioned, without discussing them in greater detail. One well known model is the balance model using scales which highlights that operations should be carried out on both sides of an equation and therefore may foster the balancing GV. In addition to this model, Filloy, Puig, and Rojano (2008) propose a geometric model for visualizing linear equations and algebraic transformations of these equations (p. 100). Within this model “algebraic expressions are represented as lengths and areas of rectangles ( $x$  and its coefficients are lengths, and their products and the independent terms are areas)” (Filloy et al., 2008, pp. 100–101) (see Figure 2). The purpose of this model within the study is to teach early algebra learners how to transform an equation, with the variable occurring on both sides of the equation, such as  $A \cdot x + B = C \cdot x$  (with  $A, B, C$  being positive integers and  $C > A$ ) into the equation  $B = (C - A) \cdot x$  (Filloy et al., 2008). This can be done by coloring and comparing areas (see

Figure 2). Ideally followed by the conclusion, that the two left over areas must be of the same size (Filloy et al., 2008).

**Figure 2:**  $A \cdot x + B = C \cdot x$  in the geometric model, with  $A \cdot x$  being colored (Filloy et al., 2008, p. 102)

Considering that the colored areas can be faded out, while focusing on the white areas, it seems like this approach embodies a subtraction of  $A \cdot x$  from both sides of the equation and therefore leads to the assumption that this model fosters the balancing GV (“*doing the same thing on both sides*”). At the same time the transformation  $A \cdot x + B = C \cdot x \Leftrightarrow B = (C - A) \cdot x$  appears to rather fit the elementary transformation rule  $A_2 + B = C_2 \Leftrightarrow B = C_2 - A_2$  than the balancing rules. Taking a closer look at the examples provided by Filloy et al. (2008) from their interviews, it is noticeable that the interviewee appears to move the expression from the left side of the equation, to the right side, while changing the sign (e.g. Figure 3). Therefore the, geometric model seems to rather foster the transposing GV than the balancing GV according to the data samples provided (Filloy et al., 2008, pp. 108–110; Filloy & Rojano, 1989, pp. 22–23).

$$15x + 13 = 16x - 15x$$

**Figure 3:** Example of a learner operating on the unknown, prior to being introduced to formal techniques of transforming equations (Filloy & Rojano, 1989, p. 110)

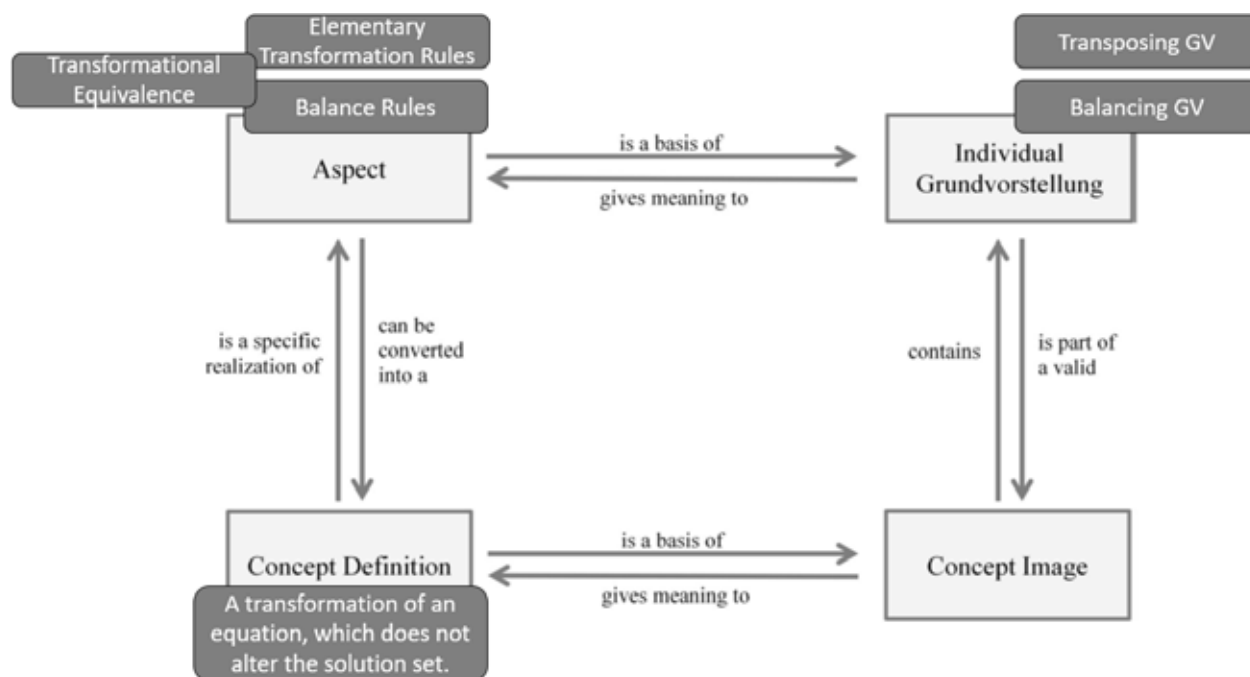

All in all, it is not possible to draw a general conclusion on what GV is fostered by the use of the geometric model. Especially when considering that the data examined here was not intended to answer which GV it fosters. None the less it should be noted that GVs are not necessarily a question of model, but of what is made of it by the individual. It is possible that another person understands this model as subtracting the same expression from both sides of an equation.

## Summary and discussion

Squaring is usually not considered an equivalent transformation of equations, although it may lead to an equivalent equation. Since this seems to be contradictory it raises the question, what does one consider to be an equivalent transformation of equations? In order to approach this question, the cognitive structure, that leads to certain assumptions, is described as concept image. Different formal definitions of equivalent transformations of equations were examined, all of which contained the idea of not altering the solution sets. Since this demand is fulfilled by squaring in the first example, this might not be what individuals consider as defining property. What seems more suitable in this case is the demand of generality, that an equivalent transformation does always maintain the solution set.

The second approach to identify factors that influence the concept image is, by using the notions of aspects and GVs. Considering that the equivalent transformations of equations should lead to equivalent equations, the transformational equivalence is examined in greater detail. This aspect requires defining valid operations, in this case the elementary transformation and the balance rules.

These two rule sets are the basis of the transposing GV and the balancing GV. Using these rules, it can be argued that squaring is not covered by them and therefore might not be captured within the aspect of transformational equivalence. Then again it can be considered using the balancing GV, that it is an equivalent transformation of equations, even then when it is not, because “you do the same thing on both sides”. Judging in which cases a transformation leads to an equivalent equation, requires the ability to recognize the equivalence of equations.

**Figure 4: Relations between aspect, Grundvorstellung, concept definition, concept, and concept image (by Greefrath et al., 2016, p. 103) applied to equivalent transformations of equations**

Discussing the geometric model of equations and transformations of equations, it was pointed out that it is not necessarily the model that indicates a certain GV, but the individual’s interpretation and use of the model. Rather than formulating a GV for every model, the approach used within this paper suggests deriving them from aspects of a given concept. This seems useful, given that different models may affect our transformation processes in the same manner. However, models cannot be abandoned, if we want to avoid that algebra learners simply perform meaningless transformations. Therefore, the GVs which are described in a rather schematic manner need to be linked to a model. It is rather the reasoning accompanying the model, than the model itself which is important.

Considering that algebraic transformations of equations are located at the transition from arithmetic to algebraic thinking (Filloy et al., 2008, p. 96), it seems like very little attention has been paid to this topic in recent research. Simply addressing it with reference to a certain model or a certain set of rules does not seem to be sufficient. More importantly is the link between models, the underlying concept and the individual, which needs to be addressed with closer regard in the future. It appears useful to examine the concept of equivalent transformations of equations in greater detail. As the discussion above shows, definitions of the concept do not necessarily grasp what is meant by equivalent transformations. But if we do not make explicit what we mean, when we talk about equivalent transformations of equations, it carries the risk that this implicit information is not acquired by the

learner. Does it not make learning and teaching more difficult? The considerations presented within this article can help identifying sources of misconceptions and give an insight to educators about limitations of definitions, rules and models describing equivalent transformations of equations.

# How students in 5<sup>th</sup> and 8<sup>th</sup> grade in Norway understand the equal sign

Hilde Opsal

Volda University College, Volda, Norway; [hilde.opsal@hivolda.no](mailto:hilde.opsal@hivolda.no)

*Having a relational understanding of the equal sign is seen as important to students in algebra in lower secondary school. The basis for their understanding of the equal sign is laid in elementary school. This paper presents results from two studies in Norway, a quantitative survey and a qualitative task-based interview. In both studies, students in 5<sup>th</sup> and 8<sup>th</sup> grade solved an equal sign task. 1230 students participated in the survey and 8 students were interviewed. These latter students also responded to questions about the meaning of the equal sign. Results from both studies show that a majority of the students in 5<sup>th</sup> grade have an operational understanding of the equal sign, while a majority of those in the 8<sup>th</sup> grade have a relational understanding of the equal sign.*

*Keywords: Equal sign, operational understanding, relational understanding.*

## Introduction

According to Ma (1999, p. 111) the equal sign is “the soul of mathematical operations” and Falkner, Levi, & Carpenter (1999) say that to understand the meaning of the equal sign is a core element to understanding algebra. In Norway, the results from TIMSS show that a major problem in mathematics is the weak results in algebra, with a significant decline in students’ performances from 2011 to 2015 in 8<sup>th</sup> grade (Grønmo, Hole, & Onstad, 2017). To prepare students in elementary school for algebra in lower secondary school, it is important to work with their understanding of the equal sign. The aim of this paper is to examine how students in 5<sup>th</sup> and 8<sup>th</sup> grade in Norway understand the equal sign.

## Operational and relational understanding of the equal sign

According to Kieran (2004), one aspect of going from arithmetical thinking to algebraic thinking is for the students to refocus the meaning of the equal sign. Prediger (2010) distinguishes between six different meanings of the equal sign, grouped into three main categories: operational meaning, relational meaning and specification. In this paper, the focus will be on the first two categories. The operational meaning is an asymmetric use of the equal sign. In elementary arithmetic, we often have a calculation to perform on the left-hand side of the equal sign that gives an answer on the right-hand side. By looking at the equal sign as “add the numbers” or “the answer”, students have an operational understanding (Knuth, Alibali, Hattikudur, McNeil, & Stephens, 2008). In the relational meaning of the equal sign, the focus is on a symmetric use of the sign. Students with a relational understanding realize that “the equal sign [is] symbolizing the sameness of the expressions or quantities represented by each side of an equation” (Matthews, Rittle-Johnson, McEldoon, & Taylor, 2012, p. 222). In arithmetic contexts, the symmetric use of the equal sign can both help to express general relations, and also numerical identities (Prediger, 2010).

Knuth, Alibali, McNeil, Weinberg, and Stephens (2005, p. 69) claim that “in algebra, students must view the equal sign as a relational symbol”. This is especially important when they learn to solve equations with operations on both sides of the equal sign. In order to understand that the transformations performed when solving an equation preserve the equivalence relation, it is essential to have a relational understanding of the equal sign. In a study of middle school students’ (6<sup>th</sup> to 8<sup>th</sup> grade) understanding of equivalence, they found that “students who have a relational view of the equal sign outperformed their peers who hold alternative views on a problem that requires use of the idea of mathematical equivalence” (Knuth et al., 2005, p. 74).

Rittle-Johnson, Matthews, Taylor, and McEldoon (2011) have made a construct map for knowledge of the equal sign as an indicator of mathematical equality, from *rigid operational* on level 1 to *comparative relational* on level 4. Students at level 1 are only successful at solving task “equations-equals-answer” and giving an operational definition of the equal sign. At level 2, *flexible operational*, students are successful at solving, evaluating and encoding atypical equation structures, for example tasks with the operations to the right of the equal sign. At level 3, *basic relational*, students can handle operations on both sides of the equal sign in equations. They can also recognize and generate a relational definition of the equal sign. At level 4, students can successfully solve and evaluate equations “by comparing the expressions on the two sides of the equal sign, including using compensatory strategies and recognizing that performing the same operations on both sides maintains equivalence” (Rittle-Johnson et al., 2011, p. 87). After using this construct map in the analysis of students’ understanding of equivalence, they comment that “describing children as having an operational or relational view of equivalence is overly simplistic” (Rittle-Johnson et al., 2011, p. 97). There may be students who are in the transition between an operational and a relational understanding of equivalence. They also noted that it was more difficult for students to give a relational definition of the equal sign than to solve equations with operations on both sides of the equal sign. In another study they also mention that the use of letters as variables instead of using blanks, may add difficulty to a task (Matthews et al., 2012).

Rittle-Johnson et al. (2011) claim that 35 years of research on elementary school students’ understanding of the equal sign shows that a majority of them have an operational understanding of the equal sign. It seems that if they get a task such as  $8 + 4 = \square + 5$ , they either add the numbers to the left of the equal sign or they add all numbers. According to Molina and Ambrose (2006), tasks like this one can only be solved correctly if the students have a “broad” understanding of the equal sign. In this study, I focus on how students answered a similar task. They were also asked about the meaning of the equal sign. Hopefully this study will provide further knowledge of the transition between an operational and a relational understanding of the equal sign. My research question is: *how do students in 5<sup>th</sup> and 8<sup>th</sup> grade in Norway understand the equal sign?*

## Methods

The data in this paper comes from two projects, one quantitative survey study and a qualitative interview study. In 2013, 1230 students in 5<sup>th</sup> and 8<sup>th</sup> grade (age 10 and 13) from two different municipalities in Norway completed a mathematics test as part of a large classroom study (Haug, 2017). The test had 40 tasks for the students in 5<sup>th</sup> grade and 52 tasks

for those in 8<sup>th</sup> grade (the same tasks as in 5<sup>th</sup> grade and in addition 12 others). Results from 584 students in 5<sup>th</sup> grade and 646 students in 8<sup>th</sup> grade will be presented in this paper. In 2018, a task-based interview (Goldin, 1993) was conducted of 8 students from other schools in Norway, 4 from 5<sup>th</sup> grade and 4 from 8<sup>th</sup> grade. The tasks used in these interviews were all multiple-choice tasks picked from the survey study. All of them had seven response alternatives, including “don’t know”. In addition to the correct answers, the rest were so-called distractors. These interviews also form part of this paper.

In this paper I mainly focus on students’ responses to one of the tasks (Figure 1). In this task they are asked about which number is hidden behind the smiley face to make the arithmetic correct. A student with an operational understanding of the equal sign may answer 9 that matches “operation equal answer” or 16 that corresponds to “add all” (taking the subtract 5 to be negative five). A student who answers correctly (2) probably has a relational understanding of the equal sign. It may also be possible for those who answer 7 or 12 to have a relational understanding. By ignoring subtraction of 5, 7 will be a correct answer and if they do not notice that there are different signs on the left- and the right-hand sides and think there is addition on both sides of the equal sign, 12 will be correct. It is unclear how students get 0 in response to this task.

21. Hvilket tall må skjule seg bak smilefjeset for at regnestykket (ligningen) skal være riktig?

$14 - 5 = \text{☺} + 7$

Vet ikke ☐

7 ☐ 12 ☐ 0 ☐ 16 ☐ 2 ☐ 9 ☐

**Figure 1: The English translation of the question is: Which number must hide behind the smiley to make the arithmetic (equation) correct? “Vet ikke” in English “Don’t know”**

## Results

The results from the survey in the equal sign task (Figure 1) show that 29.6% of the students in 5<sup>th</sup> grade and 62.2% in 8<sup>th</sup> grade gave a correct answer (2) to this task (Table 1).

	7		12		0		16		2		9		Don’t know	Total
	N	%	N	%	N	%	N	%	N	%	N	%	N	%
5 <sup>th</sup>	14	2.4	13	2.2	0	0.0	100	17.1	173	29.6	250	42.8	34	5.8
8 <sup>th</sup>	13	2.0	8	1.2	3	0.5	42	6.5	402	62.2	149	23.1	29	4.5

**Table 1: Result of the equal sign task in the survey study**

These students probably have a relational understanding of the equal sign. The result shows also that the answer that most students in 5<sup>th</sup> grade have chosen is 9 (42.8%). This corresponds to calculating what is on the left of the equal sign. Of the 8<sup>th</sup> grade students, 23.1% chose this answer. We also note that the answer with the second highest percentage of incorrect answers among the students is 16, which corresponds to “add all”. In total, 17.1% in

5<sup>th</sup> grade and 6.5% in 8<sup>th</sup> grade chose this incorrect answer. This means that approximately 60% of students in 5<sup>th</sup> grade and 30% of those in 8<sup>th</sup> grade in this study probably have an operational understanding of the equal sign.

There are 4.6% in 5<sup>th</sup> grade and 3.2% in 8<sup>th</sup> grade who answer either 7 or 12. Since only 3 students in 8<sup>th</sup> grade answer 0, this may indicate that there are few students just guessing an answer. If many students had simply guessed, this answer option would probably also have been chosen by more of them.

As mentioned earlier, a task-based interview was conducted where 8 students were asked to solve the equal sign task. Their names are fictional and the transcripts are translated into English by the author. First, all students were given another task: Calculate  $275 - 84 =$  . Three of those in 5<sup>th</sup> grade and all four in 8<sup>th</sup> grade solved this task without any difficulties. One student, Knut, had problems performing the subtraction algorithm he had chosen to use.

The second task they were given was the equal sign task (Figure 1). First, I will present the results from the students in 5<sup>th</sup> grade.

The first student, Leif, answered 16.

Leif: Ok ... 14 minus one 5 is equal ... plus ... yes ok ... 14 minus 5 that's 9 and 9 plus 7 is 16 [ticks the box with 16] ... ..

Interviewer: That sign there [points to the equal sign in the task] ... what does that mean? ... the sign before the smiley

Leif: Equals? [In Norwegian: Er lik]

Interviewer: Equals. What does that mean?

Leif: It means that it will be ... it's equal ... it should be just the same answer as it is on the other side

Leif then suggested the answer 7, before stating “this was difficult”. When the student solved this task, he showed an operational understanding of the equal sign. But when explaining the meaning of “equals”, he said that it should be similar to what is on the other side, seeing a relation between the left- and the right-hand side of the equal sign. Based on only this one task it is difficult to say whether he has an operational or relational understanding of the equal sign. Perhaps he is a student in the transition between operational and relational understanding.

Olav answered 9 in the equal sign task

Interviewer: How did you think?

Olav: Because 14 minus 5 it becomes 9 ... ..

Interviewer: What does that sign mean?

Olav: Equals

Interviewer: Equals. What does that mean? Do you know ... can you say anything more than that means equals?

Olav: Like, if you take 1 plus 1 ... then you always have equals because there should be some answer

Interviewer: In order for there to be some answer, yes ... when there is 7 at the end there, what does it mean? Did you>

Olav: < It means that the answer is 9, but then you add 7 afterwards ... then it will be 16

Olav showed an operational understanding of the equal sign both when solving the task and when explaining the meaning of the equal sign. For him the answer was on the right-hand side and the operations on the left of the equal sign. Another student, Knut, showed an operational understanding of the equal sign. He “added all numbers” and answered 16 in this task. On the question of what equals means, he responded “the answer is there”.

Arne answered 12 in the equal sign task.

Interviewer: How did you think?

Arne: Em ... since 4 minus 5 is 9 ... then the answer must be something ... which is under 10 ... so then I thought ... I don't know, I just chose something

Interviewer: You just chose 12?

Arne confirms it with a “yes”. Interviewer then asks about the meaning of the equal sign.

Arne: Equals?

Interviewer: Equals. What does that mean?

Arne: For example, if there is 3 plus 3 then it's 6 ... so then you take equals and then 6

Interviewer: ... That plus 7 there [points to the task] ...

Arne: Mm ... I just thought that ... but I think I thought wrong because that ... I thought I took 2 from there [points to 14 in the task] and gave it to the five and then it became 7 and then I thought what was there then it became 12. But it is ... it's a bit wrong

This student at first tried to explain his thinking when solving the task, then he said he just picked an answer. When asked about the meaning of equals, he gave a concrete example, indicating an operational understanding of the equal sign. Afterwards, he came up with a new explanation of how he solved this task. By subtracting 2 from 14 and adding this 2 to 5 to get 7, he had 7 on both sides of the equal sign. Since he now had 12 on the left-hand side of the equal sign, he thought the answer must be 12. This would be a correct answer if there were addition on both sides of the equal sign. What Arne explained here is an attempt to make the left- and right-hand sides of the equal sign equal. This second explanation indicated that he might have a relational understanding of the equal sign.

Three of the four interviewed students in 8<sup>th</sup> grade gave a correct answer to this task. These three connected the task to solving an equation, something they know how to do. I will only present a short extract of what they said that shows this.

Lise: [write 2] Well, I thought of the smiley as an  $x$ . Then I used the move-swap rule and changed plus 7 to minus 7. Then I took 14 minus 5 minus 7

...

Kari: ... 4 minus 5 is 9. In order for it to be 9 on the other side, there must be 2 ...

Interviewer: Yes, what did you mean by 9 on the other side?

Kari: 14 minus 5, that is 9 ...and an equation ... equal on both sides

...

Nils: ... equation yes ... 14 minus 5 is equal ... yes 14 minus 5 it's now 11 ... 4 mi [interrupt] no ... 14 minus 5 no not 11, 9 is ... and then it must be 2

These three students could solve tasks with calculations on both sides of the equal sign. Two of them said that we must have the same on both sides of the equal sign. Lise solved the task by using rules she had learned about how to solve equations. She was not asked about the meaning of the equal sign. The fourth student in 8<sup>th</sup> grade, Sven, had problems solving this task. After reading the task he first asked about the “plus 7”. Afterwards, he commented that he had seen such tasks before, and then he answered 9 because “14 minus 5 equals 9”. At the end of the interview, we returned to this task and asked him more about it. First the interviewer reminded him about the answer he gave earlier.

Interviewer: But what does plus 7 means?

Sven: No, I don't know ... oh yes, I'll add 7 or something ... ..

Interviewer: If you look at the sign before the smiley [points to the equal sign], what does that sign mean?

Sven: Equals

Interviewer: Yes ... and what does equals mean?

Sven: Aa ... no, I have never thought about that. I don't know

Interviewer: No ... when you see such a sign in your book, what do you think?

Sven: That I will write the answer before

It looks as if this student has an operational understanding of the equal sign. He has not thought about the meaning of the equal sign, even though he has most likely been taught how to solve simple equations.

## Discussion, conclusion and implications

In order to answer the question as to how students in 5<sup>th</sup> and 8<sup>th</sup> grade in Norway understand the equal sign, I have presented results from a quantitative survey. These show that approximately 60% of the students in 5<sup>th</sup> grade and 30% in 8<sup>th</sup> grade give an answer to an equal sign task which corresponds to “operational equal answer” or “add all”. These students most probably have an operational understanding of the equal sign, according to Rittle-Johnson et al. (2011). 29.6% of the students in 5<sup>th</sup> grade and 62.2% in 8<sup>th</sup> grade respond correctly to this task. These students have a “broad” understanding of the equal sign, most

likely a relational understanding (Molina & Ambrose, 2006). These results are in line with what 35 years of research have shown (Rittle-Johnson et al., 2011). A higher percentage of students in 8<sup>th</sup> grade than in 5<sup>th</sup> grade respond correctly to this task. The reason for this may be that those in 8<sup>th</sup> grade have worked more with equations and in so doing they might have developed a relational understanding of the equal sign. It may also be the case that they have acquired a mechanical way of solving this kind of tasks (which maybe Lisa has).

The results from the task-based interviews showed that there were students who displayed an operational understanding of the equal sign, both in the way they solved this equal sign task and in the explanation they gave of what the equal sign means. What is more interesting is what was revealed in the interviews with the students Leif and Arne. In solving this task, Leif showed an operational understanding of the equal sign. But when asked what the sign means, he came up with an explanation saying that the left- and right-hand sides of the equal sign must be equal. For Arne, it is the opposite. He explained the equal sign with a concrete example, indicating an operational meaning of the equal sign. But when he solved the equal sign task, he seemed to confuse the subtraction sign with an addition sign on the left-hand side of the equal sign. That gave him a wrong answer, but the explanation he gave would be correct with the correct calculation sign. Leif and Arne were the two interviewed students in 5<sup>th</sup> grade who seemed to be closest to a relational level. With these two students we saw there was a difference between using a relational strategy when solving equal sign tasks and expressing a relational understanding of the equal sign.

Based on the construction map for knowledge of the equal sign as indicator of mathematical equality, developed by Rittle-Johnson et al. (2011), we saw that all the students who completed the first task in the interviews were at least at the rigid operational level. They were able to solve a task with an operation on the left-hand side and the answer on the right-hand side of the equal sign. Of the four interviewed in the 8<sup>th</sup> grade, three were able to solve the equal sign task and two of them used argumentation about the two sides being equal. These two students were probably at a relational level (either level 3 or 4). They are able to solve a task with operations on both sides of the equal sign and they reveal a relational understanding of the equal sign. Two of the 5<sup>th</sup> grade and one of the 8<sup>th</sup> grade students interviewed may be in the transition between operational and relational understanding of the equal sign.

Despite many years of research on the importance of students at early age developing a relational understanding of the equal sign, this study shows that it does not appear that there has been any progress in Norway with regard to students' understanding of the equal sign. In today's curriculum, the equal sign is not explicitly mentioned. But in Norway, a new curriculum will come into effect in 2020 that applies to 1<sup>st</sup> to 13<sup>th</sup> grade. A first draft of the new curriculum was out for consultation in the autumn of 2018. One of the competence aims for 3<sup>rd</sup> grade states that the students should be able to use equality and inequality in comparing quantities, expressions and numbers, using the equal sign and unequal sign and giving reasons for their choice. If the proposal for a new competence goal is passed, then perhaps we can hope that more students will acquire a relational understanding of the equal sign.

## Acknowledgements

The quantitative study was supported by the Research Council of Norway under Grant 218326; Volda University College; and Inland Norway University of Applied Science. The qualitative study was supported by Volda University College and conducted in cooperation with my colleagues Odd Helge M. Tonheim and Arne Kåre Toppol. Neither of these studies would have been possible without all the students who so willingly participated.

*The aim of this study was to investigate the effect of a six-lesson teaching intervention on fifth-grade students' linear equation solving abilities. A hanging mobile, a balance model consisting of a horizontal beam with on each side a number of bags hanging on a chain, played a central role in this intervention. In total, 213 fifth-graders participated in one of the two intervention conditions or in the control condition. The intervention conditions differed with respect to the type of hanging mobile; either a physical hanging mobile that students could manipulate or a static version on paper. Preliminary analyses of the scores on the pre- and post-test seemed to show an improvement in students' linear equation solving abilities for students in both intervention conditions. Students, who worked in an embodied learning environment with a physical hanging mobile, seemed to show more improvement than students who worked with a paper-based mobile.*

### Introduction

The importance of laying the foundation for learning algebra at a young age is increasingly being emphasized. (e.g., Kaput, Carraher, & Blanton, 2008; National Council of Teachers of Mathematics [NCTM], 2000). A large number of studies have provided evidence that, by taking students' natural, intuitive ideas and informal reasoning as an entry point, students of primary school age can already engage in algebraic thinking (e.g., Kaput et al., 2008). Research in this area of *early algebra* has revealed that several algebraic concepts such as equivalence, expressions, equations, inequalities, generalized arithmetic, functional thinking, variable, and proportional reasoning can be taught to young students (Blanton, Stephens, Knuth, Gardiner, Isler, & Kim, 2015). In the current study, we investigated how linear equation solving of fifth-graders can be fostered.

### Teaching linear equation solving

Studies on early algebraic thinking often investigated students' linear equation solving ability. These studies generally found positive results. It was for example found that third-grade students can successfully deal with equation-related concepts such as equality and the equal sign, crucial for

learning to solve linear equations (e.g., Bush & Karp, 2013), can solve simple equations such as  $3 \times n + 2 = 8$ , and can use letters to represent unknown quantities (Blanton et al., 2015). Moreover, when starting from a meaningful context, 10-year old students were found to be able to represent, meaningfully discuss, and solve equations with unknowns on both sides of the equal sign (Brizuela & Schliemann, 2004), and, through informal reasoning, sixth- and seventh-grade students have even shown themselves able to solve systems of linear equations (Van Amerom, 2003; Van Reeuwijk, 1995). However, there are only a limited number of studies in which young students had to solve systems of equations and those that were carried out were not set up systematically and contained small samples of students.

A frequently used model to make linear equation solving more accessible to young students is the balance model. This model can support students in different ways when solving linear equations and is particularly deemed suitable for grounding the equality aspect of an equation, as such enhancing the conception of the equal sign as a symbol for representing equality (Otten, Van den Heuvel-Panhuizen, & Veldhuis, 2019). The balance model also can assist students in providing a language base for solving problems, as was shown by Warren and Cooper (2005) in a study involving third-grade students. Furthermore, by means of providing a meaningful context, it can help students to handle problems with unknowns (Gavin & Sheffield, 2015).

### **Role of physical experiences in learning mathematics**

Considering the role of physical experiences for learning has a long tradition. For example, Piaget (Piaget & Inhelder, 1967) already assumed that actions form the basis for learning and are important for understanding abstract ideas. A recent study on the efficacy of teaching mathematics through the use of manipulatives, showed benefits for instruction with manipulatives especially for children aged 7-11 and for the mathematical domain of algebra, compared to children that received abstract symbolic instruction (Carbonneau, Marley, & Selig, 2013). Using manipulatives has also been found to be beneficial for young students to learn to solve simple symbolically presented equations (Sherman & Bisanz, 2009).

Since the emergence of theories of embodied cognition, the attention for physical experiences in learning has been renewed (De Koning & Tabbers, 2011). According to embodied cognition theories, bodily experiences are essential for cognitive learning processes (e.g., Wilson, 2002) and abstract higher-order cognitive processes, such as mathematics, are assumed to be grounded in action and perception (Barsalou, 1999). Hence, embodied learning environments are regarded as important for learning mathematics (Abrahamson & Lindgren, 2014).

### **Current study**

In the current study, we investigated the effects of an intervention, consisting of a six-lesson teaching sequence, on fifth-grade students' linear equation solving abilities. The intervention was based on the idea that embodied learning environments can be beneficial for learning mathematics. A hanging mobile, a balance model consisting of a horizontal beam with on each side a number of bags hanging on a chain, played a central role in this intervention. In this study, we formulated the following research questions: *(1) What is the effect of an intervention based on a balance model on*

*students' linear equation solving performance? and (2) What is the difference between the effect of an intervention based on a balance model with a manipulable physical hanging mobile from that with a static hanging mobile on paper on students' linear equation solving performance?*

## Method

### Research design

To investigate these questions, we set up a classroom experiment based on a staged comparison design consisting of two intervention conditions and a control condition. In the first intervention condition, a physical hanging mobile was used that students could manipulate. In the second intervention condition, a paper-based hanging mobile was used. For each condition there were three cohorts, which differed in the timing of the intervention. In each cohort the students' performance on linear equation solving was measured four times (see Table 1). Each measurement contained the same test items. Making use of a staged comparison design made it possible that the same teacher taught all the lessons of the interventions.

Condition	Cohort ( <i>n</i> )	Measurement 1 Oct. 2016	Nov.-Dec. 2016	Measurement 2 Dec. 2016	Feb.-March 2017	Measurement 3 March 2017	May-June 2017	Measurement 4 June 2017
Intervention Condition 1	Cohort 1 ( <i>n</i> =22)	<b>M1</b>	Intervention	<b>M2</b>		M3		M4
	Cohort 2 ( <i>n</i> =18)	M1		<b>M2</b>	Intervention	<b>M3</b>		M4

	Cohort 3 ( <i>n</i> =25)	M1		M2		<b>M3</b>	Control intervention	<b>M4</b>

**Table 1: Research design. For the current study we focus on the measures in bold**

### Participants

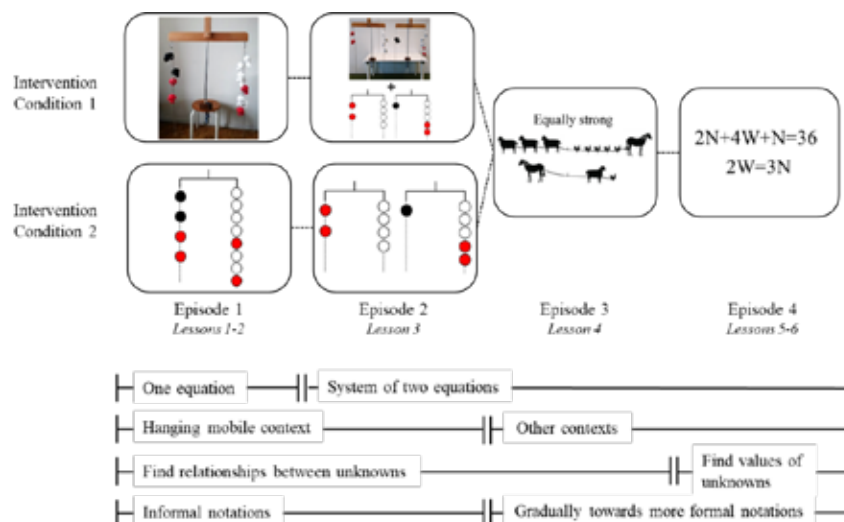

Participants included 213 students (47% boys), with ages ranging from 9 to 11 ( $M = 10.04$ ,  $SD = 0.49$ ) from nine fifth-grade classes in seven schools in the Netherlands. The classes were selected by convenience. Three classes participated in Intervention Condition 1 ( $n = 65$ ), three classes in Intervention Condition 2 ( $n = 68$ ), and the final three classes formed the Control Condition ( $n = 80$ ). Students had received no prior instruction on equation solving or other algebra topics.

### Intervention program

In both intervention conditions students were taught linear equation solving by means of the same four-episode (six lessons) teaching sequence (see Figure 1). The lessons were taught by the first author of this paper. The overall aim of this sequence was to elicit algebraic reasoning related to

(informal) linear equation solving. In each of the episodes the aim was to provide students with opportunities to develop algebraic strategies related to linear equation solving, such as restructuring strategies (e.g., change the order of terms in an expression, exchange the expressions on both sides of the equation), isolation strategies (i.e., strategies to isolate an unknown, such as taking away similar things on both sides), and substitution strategies (i.e., replacing unknowns by other unknowns or by values). In the first episode, students worked with one hanging mobile to discover relationships between unknowns and were thus reasoning about one equation. Students' main task was to discover all possible ways to maintain the balance of the mobile, for example by exchanging the bags of the left and right side of the mobile, by taking away similar bags from both sides, or by substituting one color of bags by another color. From Episode 2 on, the information from two equations had to be combined to discover relationships between unknowns to solve the problems. Students were thus reasoning about a system of equations, first still in the context of the hanging mobile (Episode 2) and then in new contexts such as a tug-of-war situation (Episode 3). From Episode 3 on, students were additionally challenged to use more symbolic notations. In the final episode, Episode 4, students had to find the values of unknowns in a system of two symbolically notated linear equations.

The two intervention conditions differed as regards whether students gained physical experiences during the teaching sequence (Figure 1). In the first episode of Intervention Condition 1, an embodied learning environment was created in which students worked in small groups (2-3 students) with a physical hanging mobile. While trying to maintain the balance of the mobile, the tilting beam could be in or out of balance, thus providing students real-time feedback on their actions while manipulating the bags. In Episode 2, students in Intervention Condition 1 worked with paper-based hanging mobiles. The physical hanging mobiles were, however, still present in front of the classroom in this episode, but not all students worked on them. Instead, the physical hanging mobiles were used during classroom discussions by the teacher or by some students to make their reasoning processes explicit. Also, in Episodes 3 and 4 the physical hanging mobile was present in front of the classroom.

**Figure 1: Schematic representation of the intervention (for both intervention conditions)**

In Intervention Condition 2, students received the exact same lessons with the exact same assignments; only the physical hanging mobile was replaced by a paper-based hanging mobile so that these students did not gain physical experiences during the lessons. Lastly, students in the Control Condition were not taught any lessons on linear equation solving. Instead they participated in a control intervention consisting of a six-lesson teaching on probability – a topic which is also not taught at primary schools in the Netherlands. Students were taught the probability lessons as a control group, so that possible differences between the intervention and control conditions could not be attributed to the fact that only in the intervention conditions students received additional lessons on a (to them) new mathematical topic.

### Test for linear equation solving

Students' performance on linear equation solving was assessed by a paper-and-pencil test, consisting of four items in which students had to solve (a system of) linear equations (see Figure 2). The same test was administered to the students repeatedly before and after the intervention (see Table 1, Measurement 1-4). The items were formulated in such a way that prior instruction on linear equation solving was not essential to solve the problems. The algebraic strategies that students developed during the lessons (i.e., restructuring, isolation, and substitution strategies) could be used to solve the problems. The open-ended questions explicitly invited students to explain their thinking and to reveal their reasoning.

**Figure 2: Test items on linear equation solving**

### Data analysis

Each linear equation solving performance item (Figure 2) was scored as incorrect (0) or correct (1), resulting in a total correctness score with scores ranging from 0 to 4. Items 2 and 4 were only scored as correct when both sub questions were answered correctly. Students' explanations were categorized by means of a coding scheme. In each test item, students had to solve the problem by combining the information of two equations. Taking the information from both equations into account and reasoning on the basis of both equations was crucial for solving these problems. In the coding scheme, we therefore coded students' level of reasoning based on their ability to incorporate information from the different equations in their reasoning process. More specifically, we distinguished between students who did not use any of the equations in the description of their reasoning (Level R0), students who reasoned on the basis of only one of the two given equations

(Level R1), and students who reasoned on the basis of both given equations by combining the information of both of them (Level R2).

For the current paper, we focus on the data of the tests directly before and after the interventions (see Table 1, measures in bold), consisting of students' correctness and reasoning scores. Mean values and standard deviations were calculated for both scores on the pre- and post-test. Effect sizes (Cohen, 1988) were also calculated for each condition.

## First results

For both intervention conditions, students' correctness scores increased. For Intervention Condition 1, the correctness scores increased from  $M = 2.31$  ( $SD = 1.17$ ) on the pre-test to  $M = 3.22$  ( $SD = 0.91$ ) on the post-test ( $d = 0.87$ ). For Intervention Condition 2, the correctness scores increased from  $M = 2.43$  ( $SD = 1.21$ ) on the pre-test to  $M = 3.15$  ( $SD = 0.93$ ) on the post-test ( $d = 0.67$ ). In contrast, students of the Control Condition almost showed no improvement on correctness scores, going from  $M = 2.65$  ( $SD = 1.26$ ) on the pre-test to  $M = 2.72$  ( $SD = 1.33$ ) on the post-test ( $d = 0.05$ ). Students' reasoning also improved for both intervention conditions (see Figure 3). When comparing pre- and post-tests, a decrease in percentage of the lowest level of reasoning (Level R0) was observable, while there was an increase in the highest level of reasoning (Level R2). The percentages of the intermediate level of reasoning (Level R1) remained more or less stable.

**Figure 3: Percentage of students showing each level of reasoning on the pre- and post-test**

When comparing both intervention conditions, students in Intervention Condition 1 showed a somewhat larger improvement than students in Intervention Condition 2, both on correctness scores and level of reasoning. For both intervention conditions, there was a decrease in percentage of the lowest level of reasoning (R0) and an increase in the highest level of reasoning (Levels R2), with a somewhat larger decrease of Level R0 and a somewhat larger increase of Level R2 for Intervention Condition 1. The percentages of the intermediate level of reasoning (Levels R1) remained more or less the same for both conditions. For the Control Condition, the percentages of all levels of reasoning (almost) did not change.

To provide an example of an individual learning process of one of the students, we zoom in on the on the pre- and post-test answers to Item 4 of Omar, who participated in Intervention Condition 1. On the pre-test, Omar gave an incorrect answer to this item, with the explanation “I don’t know”. This response was categorized as Level R0, because he did not use any of the given equations in his

explanation. His answer on the post-test is shown in Figure 4. Here, Omar interestingly represented the equations as hanging mobiles. Then he doubled the second equation ( $S + P = 10$ ) to substitute this in the first equation ( $S + S + S + P + P = 27$ ), so that unknown  $S$  was isolated. In this way he found that  $S$  equals 7 and then used the second equation to find the value of  $P$ . Omar's solution strategy was categorized as Level R2, because he reasoned on the basis of both given equations by combining the information from both equations.

**Figure 4: Solution strategy of Omar (translated from Dutch) on the post-test; categorized as Level R2**

## Discussion

Based on these first results, we can draw the tentative conclusion that our six-lesson intervention in which the balance model in the form of a hanging mobile plays a central role, can improve students' linear equation solving abilities. Moreover, our descriptive data indicate that when this intervention took place in an embodied learning environment in which the students could work with a physical hanging mobile instead of with a version on paper, the performance gain was even larger. This latter finding is in line with the idea that embodied learning environments are beneficial for learning mathematics (e.g., Abrahamson & Lindgren, 2014), and it could add to the use of these environments in whole classroom settings. To be more certain about what we can learn from our study more advanced statistical analyses will be carried out.

*This paper describes the differences in the types of representations used by eight third-grade (8 to 9-years-old) and eight fifth-grade (10 to 11-years-old) students when working with problems that involve different linear functions. We present an analysis of students' written and oral answers during a Classroom Teaching Experiment (CTE) and semi-structured interviews from a functional approach to early algebra. The study examines how students' representations varied when working with different types of linear functions ( $y = x + a$ ;  $y = ax$ ;  $y = ax + b$ ), when solving for specific values, and when generalizing. The findings show that students in both grades primarily used the representation present in the problem. The type of linear function involved appears to have had no effect on either group's use of one representation or another.*

**Keywords:** Representation, generalization, linear functions, functional thinking.

## Introduction

Functional thinking—which has been found to facilitate the introduction of algebra in the early grades—focuses on the relationships between two or more covarying quantities (Blanton, Brizuela, Gardiner, Sawrey, & Newman-Owens, 2015); these relationships can be expressed through different representations. Representations, which form an integral part of how students think about functions, “can denote and describe material objects, physical properties, actions, and relations, or things that are far more abstract” (Goldin & Shteingold, 2001, p. 4). Therefore, representations help to structure and expand students' thinking (Brizuela & Earnest, 2008). Broadly, our interest is focused on types of representations used by elementary students when working with covarying quantities.

Some researchers have described how elementary school students working with problems that involve single linear functions use, represent, and understand the relationships involved in a given problem (e.g., Brizuela & Earnest, 2008). The originality of this study lies in the exploration of the types of representations used by elementary school students when working with problems involving different types of linear functions. More specifically, this paper analyzes the answers given by eight third- and eight fifth-grade students participating in a CTE, and their answers in semi-structured interviews, after the CTE. The research question is: how do students' representations vary when working with different types of linear functions? Based on this research question, we define two specific aims to describe the type of representations used by these students when: (a) solving problems which involved three types of functions:  $y=x+a$ ;  $y=ax$ ; and  $y=ax+b$ ; and (b) answering questions regarding specific values and when asked to generalize the relationship between variables.

## Background

The relationship between generalization and representation is central: both are intrinsic to algebraic thinking and consequently to functional thinking. According to Kaput, Blanton, and Moreno (2008),

representations—a socio-cultural vehicle used to generalize—enable students to build and complete the ideas that help them reason about general statements and compress multiple instances into the unitary form of a single statement that symbolizes the multiplicity. Thus, generalization is the “act of creating that symbolic object” (p. 20).

Several studies highlighted the role of representations in generalizing the relationship between two variables. According to some findings, 8 to 10-years-old students, instructed to use algebraic notation, represented the linear relationship  $y=x+a$  by mainly using algebraic notation rather than natural language (Carraher, Schliemann, & Schwartz, 2008), while other studies reported that fifth graders (10 to 11-years-old) spontaneously used algebraic notation to generalize a problem that involve  $y=mx+b$  (Pinto & Cañadas, 2018). Another study distinguished between the representations used by students when working with specific values and when generalizing, concluding that students who do not use algebraic notation when they represent a generalization do “not yet have a representational means to compress multiple instances into a unitary form that could symbolize these instances” (Blanton et al., 2015, p. 542). Further research is therefore needed on how the representations used by students vary when working with different linear functions, and how they differ depending on whether they are working with specific values or generalizations.

The types of representations that can be used by elementary school students to solve problems involving linear functions include: (a) natural language – oral; (b) natural language – written; (c) pictorial; (d) numerical; (e) algebraic notation, (f) tabular; and (g) graphic (Carraher et al., 2008). Considering the suggestions of early algebra literature, we stress the role of natural language because it is considered as a useful scaffold to understand symbolic representations (Kaput, 1987; Radford, 2003), and helps to broaden students’ understanding about functions, improving their abilities to solve problems (MacGregor & Stacey, 1995).

## Method

This study forms part of a broader project that explores functional thinking among elementary school students in Spain.

## Students

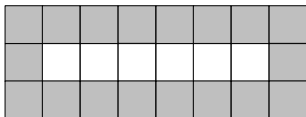

Two groups were intentionally selected for the first year of the study: 24 third-grade (8 to 9-years-old) and 24 fifth-grade (10 to 11-years-old) students. The students had not worked previously with such problems. Then, we interviewed eight students in each group to obtain a deeper understanding of how they responded to problems involving relationships between two variables.

## Data collection: CTE and interviews

The data were collected during the CTE and individual interviews. The CTE and interviews objectives were to: (a) explore how students relate the variables involved in a problem involving a linear function; (b) introduce different types of representations to express functional relationships; and (c) explore students’ generalization when working with functional thinking tasks.

A four-session CTE was designed for each grade during the last term of 2014/2015 period, with each session lasting approximately 60 minutes. Each CTE session was divided into three parts. First, we introduced the context of the problem, highlighted the representations given and asked the students

questions about specific values to ascertain whether they had understood it. Second, the students were given individual worksheets with questions about specific values and generalization related to the problem. Third, the researchers led a classroom discussion around the responses to some of the questions on the worksheets. During the 2015/2016 period, eight students from each grade were interviewed in two 30-minute interviews. The interviewees were deliberately selected to include children who had performed differently during the CTE and it provided a way to more closely detail individual students' representations from the CTEs. Table 1 shows the general context of problems posed, types of functions, and types of representations introduced during the CTE and interviews.

**Table 1: Problems posed in CTE and interviews**

The problems proposed involved different linear functions ( $y=x+a$ ,  $y=ax$ , and  $y=ax+b$ ); some of them were selected from previous studies and others were designed by the research team, considering different types of linear functions. The questions concerning each problem were sequenced according to the inductive reasoning model of Cañadas and Castro (2007), which structures questions from specific values to generalization. For instance, the fourth task for third and fifth grade included questions regarding:

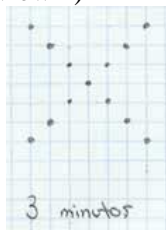

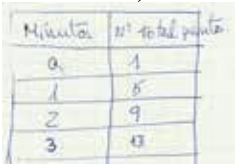

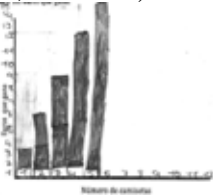

- Specific values. For example, “How many grey tiles do they need for a corridor with 10 white tiles?”, and

- Generalization. For example, “The workers always lay the white tiles first and then the grey tiles. How can they calculate how many grey tiles they need in a corridor where they’ve already laid the white ones?”

The data analyzed in this paper were the students’ CTE and interview worksheets and the transcriptions of the video-recorded interviews.

### Data and analysis categories.

The first step was identifying the types of representations used by the students. Figure 1 gives an example of each type of representations<sup>1</sup> used by students when they answered in different tasks.

<b>Natural language - oral</b> (Fourth grade, Interview 2) Interviewer: How would you find the number of passengers for any number of stops? Student: (...) <i>multiplying that number times three plus one.</i>	<b>Natural language – written</b> (Third grade, CTE, session 1) We found a picture of Raúl’s birthday party and all you can see are the candles on the cake. How could you find María’s age? <i>I add five to Raúl’s age.</i>	<b>Pictorial</b> (Sixth grade, Interview 1) 	<b>Numerical</b> (Third grade, CTE, session 1) When Raúl is 15, how old will María be? <i>Raúl’s 15 and María’s 20.</i> How did you find your answer? $15+5=20$
<b>Algebraic notation</b> (Fifth grade, CTE, session 4) How many grey tiles do they need for a floor with five white tiles? <i>They need 16 grey tiles.</i> <i>Formula: <math>(X \times 2)+6=16</math>.</i> <i><math>X</math> = number of grey tiles</i>	<b>Tabular</b> (Fourth grade, Interview 1) 	<b>Graphic</b> (Third grade, CTE, session 3) 	

**Figure 1: Examples of types of representation in students’ answers**

The representations used by the students to solve problems were first identified and then analyzed considering: the type of linear function in each problem ( $y=a+x$ ,  $y=ax$ , and  $y=ax+b$ ), and the students’ answers when working with specific values and when generalizing.

## Results and Discussion

We present the findings for the types of representations used by each group of students, considering our research questions.

### Third and fourth grades

Table 2 lists the frequency for each type of representations used by students in CTE and interviews, considering different linear functions and when working with specific values and when generalizing.

<sup>1</sup> Which were not mutually exclusive.

	Representation	CTE			Interview	
		$y=x+a$	$y=ax$	$y=ax+b$	$y=x+a$	$y=ax+b$
Specific values	N-oral				8*	7*
	N-written	2*	4*	5*		
	Pictorial					
	Numerical	4	7	6	1	7
	Algebraic	4*	5*			
	Tabular				1	2
	Graphic					
Generalization	N-oral				7*	6*

	Pictorial					
	Numerical					
	Algebraic				6*	5*
	Tabular					
	Graphic					
* = representation introduced in the problem itself						

**Table 2: Representations used by third- and fourth-graders**

As the data in Table 2 shows, the students tended to use the representation introduced in the problem itself, regardless of the type of linear function involved. Specifically, oral and written natural language prevailed in this group of eight students. Mario's response during the first interview to a problem with a function of the type  $y=x+b$  is an example.

Interviewer: Let's suppose I don't know how many hours I'm going to park, but I tell you that I'm going to be there for  $x$  hours (...). How can I know how much it's going to cost me?

Mario: (...) Well, if you're there for  $x$  hours, you add 2. For all the hours [the car is parked] you add 2.

As exemplified in the above extract, the prevalence of oral language is an essential element in learning to recognize and understand a function (MacGregor & Stacey, 1995). The use of a numerical representation was also observed at least once in all the problems involving specific values. This makes sense, since students were being asked about specific, and not general values. Numerical representation was as frequent as natural language in students' answers to problems with functions of the form  $y=ax+b$ .

During the interviews one year later, some students spontaneously arranged the values of the variables in tabular form. Figure 2 shows how Susana arranged the data to explore the specific values in a problem of the type  $y=mx+b$  (interview 2).

3	10
4	13
5	16
6	19
7	22
8	25
9	28
10	31

**Figure 2: Susana's answer when working with specific values**

As Figure 2 shows, Susana arranged the specific values in two columns separated by a dash (-). She listed the number of stops on the left and the number of people on the train on the right. This table, according to Martí (2009), shows that “data be organized (categorization, establishing correspondences) in a certain spatial layout” (p. 134). Susana’s table is a novel way to represent, relate and understand the values involved in the problem. Spontaneous tabular representations were observed during the interviews in the problems involving functions such as  $y=x+a$  and  $y=ax+b$ .

The eight students used different representations depending on whether they were working with specific values or generalizing. During the CTE, the variety of representations was wider when they were exploring the relationship with specific values (written natural language, numerical, algebraic notation) than when generalizing, when they used written natural language only. One possible explanation for this difference may lie in the complexity inherent in generalizing the relationship between two variables, as suggested by other authors (e.g., Radford, 2003). Nonetheless, natural language would appear to be the way these students explain general rules. During the interviews, the students used the representation present in the problem to generalize the relationship, whereas for specific values they used numerical and tabular representations as well.

### Fifth and Sixth Grades

Table 3 lists the types of representations used by the eight students in this group, when solving the problems posed.

	Representation	CTE			Interview		
		$y=x+a$	$y=ax$	$y=ax+b$	$y=x+a$	$y=ax$	$y=ax+b$
Specific values	N-oral				1	1*	1*
	N-written	1*		5*			
	Pictorial			3*	5*		
	Numerical	5	2		2	4	4
	Algebraic			1			
	Tabular				6*	3*	4*
	Graphic						
Generalization	N-oral				4*	3*	3*
	N-written	3*	4*	7*			
	Pictorial						
	Numerical		1	1	1	1	1
	Algebraic	2*	3*	2	5*	3	4*
	Tabular						
	Graphic						
Note. * = representation introduced in the problem itself							

**Table 3: Representations used by fifth and sixth graders**

We can see in Table 3 that these students tended to use the same type of representation as introduced in the problem. Significantly, in the tiles problem (CTE,  $y=mx+b$  type function), two of the students used algebraic notation spontaneously. Camila’s answer to the first question associated with that problem is reproduced in Figure 3.

1. How many grey tiles do they need for a floor with five white tiles?  
*They need 16 grey tiles. Formula:  $(X \times 2) + 6 = 16$ .  $X$  = number of grey tiles*

**Figure 3: Camila's answer to the tile problem (CTE, session 4)**

Camila used a representation not introduced in the problem. Although some of the questions posed in the earlier sessions involved the use of algebraic notation, here the student used it to express the general rule, although she was answering a question about a specific value. This type of representation was also observed in the interviews, specifically in four students' answers to the problem in the second interview, in which the functions were of the type  $y=ax$  and  $y=ax+b$ . That spontaneous use of algebraic notation differed from the findings for the third- and fourth-grade students and suggests that some of the sixth graders were quicker to adopt the use of algebraic notation to express general relationships between two variables.

Most of the students in fifth and sixth grades generalized using (oral or written) natural language or algebraic notation, whereas for specific values they used a wider variety of representations (oral and written natural language, pictorial, numerical, algebraic notation and tabular). Numerical representation prevailed in these students' solutions to the specific value questions. Once again, this make sense given that were being asked about specific values.

## Conclusions

This paper seeks to shed light on how the representations used by intermediate and upper elementary school students (8 to 12-years-old) vary when solving problems that involve different types of linear functions. Specifically, in both groups, when the students generalized the functional relationship, they used the same type of representation as introduced in the problem (natural language or algebraic notation). The variety of representations was broader when they worked with specific values. These findings reveal that while they were aware of different types of mathematical representations (used when working with specific values), when generalizing they only used two. As noted by other authors (e.g., Brizuela & Earnest, 2008), this highlights the importance of teaching representations in elementary school to enable students to gradually assimilate them as they are constructing meaning for different types of representations when generalizing and grasping the meaning of functional relationships.

Concerning this study's specific objectives, no major differences were observed in the representations used in one type of function or another by either third- and fourth- or fifth- and sixth-graders. That may be because both groups had participated in a CTE in which they solved problems involving different linear functions. Tabular representations appeared spontaneously in some of the third/fourth-grade students' answers, whereas algebraic notation appeared among the fifth/sixth-graders. Significant use of numerical representation was found in both groups and it was consistent with what the problem asked them. The major difference between the two groups was in the types of representations used when working with specific values and when generalizing. When generalizing, the third- and fourth-graders used a narrower variety of representations than the older group of students. This seems to suggest that in this sample, the students in the higher grades of elementary school had more resources from which to draw when expressing general rules.

## Acknowledgment

This study was funded by the Spanish Ministry of Economy and Competitiveness under National R&D Project EDU2016-75771-P; the first author benefited from a PhD. grant awarded by the Chilean Government through the CONICYT, folio 72160307-2015.

*The purpose of the present study was to propose and empirically validate a model describing secondary school students' algebraic thinking. Based on a synthesis of the literature, a model for Grade 9 students' algebraic thinking was formulated. The major constructs incorporated in this model were "generalized arithmetic", "transformational ability" and "meta-algebra". The study involved one hundred fourteen students. Data analysis validated the hypothesized model and suggested a sequential effect between the three factors. Transformational ability had a direct effect on generalized arithmetic and the latter had a direct effect on meta-algebra.*

*Keywords: Algebra, algebraic thinking, secondary school algebra, functional thinking.*

## Introduction

Recently, there is a growing consensus that algebra is the gateway to school mathematics reform for the next century and school algebra should be reformulated as a K-12 strand of thinking (Kaput, 2008; National Council of Teachers of Mathematics, 2000; Stephens, Ellis, Blanton & Brizuela, 2017). Algebraic thinking can be coherently conceptualized as a synthesis of different content strands, concepts, processes or forms of reasoning that relate to the ideas of equivalence, generalized arithmetic, variable, proportional reasoning, modelling, and functional thinking (Blanton, Stephens, Knuth, Gardiner, Isler, & Kim, 2015; Chimoni, Pitta-Pantazi, & Christou, 2018).

A number of researchers provided diverse conceptualizations of algebraic thinking, focusing on different parameters (Drijvers, Coddijn, & Kindt, 2011). One of the most influential developments of the past decades in respect to conceptualizing the notion of algebraic thinking is Kaput's organizing framework (Stephens et al., 2017). Kaput (2008) suggested that algebraic thinking consists of two core aspects: (a) generalizing and representing generalizations and (b) syntactically guided reasoning and actions on generalizations represented in conventional symbolic systems (Stephens et al. 2017). Kieran (2004), adopting a different methodology, conceptualized algebra as a multifaceted activity that encompasses various types of tasks and ways of thinking. Kieran offered a slightly different view by arguing that algebraic thinking is not only about using symbols in order to express generality; algebraic thinking arises when individuals make use of any kind of representations when they try to manipulate quantitative situations in a relational way. Drijvers, Coddijn and Kindt (2011) provided a different conceptualization of algebraic thinking giving emphasis on the role of functional thinking and solving equations and in-equalities with reference to specific constraints.

Thus, researchers' efforts to describe algebraic thinking through several perspectives are characterized by diversity and there is not a consensus regarding the dimensions of students' algebraic thinking in secondary school (Carragher, Martinez & Schliemann, 2008). In addition, the existing models are based mainly on theoretical conceptualizations of students' algebraic thinking. The aim of this study is the development of a better understanding of the notion of secondary school students' algebraic thinking by proposing a model that takes into consideration existing and well-accepted theoretical frameworks (Kaput, 2008; Kieran, 2004). Thus, the proposed model is founded by

utilizing aspects of algebraic thinking that are well-accepted in the existing literature. In addition, the proposed model will be validated based on empirical data.

## Literature Review

Several researchers made efforts to analyse the nature and content of algebraic thinking. There are differing views on what constitutes algebraic thinking, but many agree that a fundamental element is generalization, that is the ability to see the general in the particular (Kaput, 2008; Kieran, 2004; Wilkie, 2016). Generalization is a cornerstone of mathematical structure, while symbolization is a catalyst of algebraic thinking development. In this paper, we examine Kaput and Kieran's models of algebraic thinking, which are considered of the most influential in recent literature (Stephens et al., 2017). Kaput (2008) asserted that generalizing and symbolizing are tightly linked in that symbols allow generalizations to be expressed in a stable and compact form, throughout three strands: (a) generalized arithmetic, (b) functional thinking and (c) modelling. Generalized arithmetic, as a way for applying algebraic thinking in arithmetical settings, involves the use of letters for generalizing rules about relations between numbers, manipulating numbers and operations properties, examining number structure, understanding the equals sign in number relations, notice relationships in operations on classes of numbers and reasoning with forms and representations of equivalence. The generalizations that students make in the realm of generalized arithmetic can serve as a context for developing students' abilities to represent mathematical ideas symbolically. Functional thinking refers to the identification and description of functional relations between independent and dependent variables in different forms of representation and the manipulation of covariance and correspondence relations. Finally, modelling involves the use of symbols for developing models, manipulating variables, and re-translating between models and situations. Emphasis is placed on exploring modelling problems that are derived from complex realistic situations (Blanton et al, 2015).

Kieran's (2004) model for conceptualizing algebraic activity denotes that algebra is not just a topic in mathematics curriculum, but a multifaceted activity that encompasses various types of tasks and ways of thinking. Kieran asserted that algebraic thinking is considered as an approach to quantitative situations that seeks to look for relationships and structure with means that are not strictly letters-symbolic. Kieran, compared to Kaput, emphasized that algebraic thinking is a way for introducing students to the more abstract aspects of formal algebra and pointed out that her model tries to unfold the kinds of meaning that secondary students make when they are engaged with algebraic tasks. This model involved three types of activities: "generational" activities, "transformational" activities, and "global, meta-level" activities. The generational activities refer to the generation of equations and expressions in various situations and involve exploration of problem situations and numerical and geometrical patterns that lead to the formulation of generalization, and exploring numerical relationships. The transformational activities refer to the transformation of expressions by applying specific rules and involve conceptual understanding of algebraic objects. The global, meta-level activities are not strictly algebraic in nature, but algebraic tools are needed to be investigated and involve general mathematical processes, such as proving, studying functional relationships and identifying structure.

In conclusion, Kaput and Kieran's models examine algebraic thinking under a different perspective. Kaput (2008) emphasized the role of generality and symbols by explaining algebraic reasoning under two core lenses: (a) symbolization that serves purposive generalization and (b) reasoning with

symbolized generalizations. Thus, in Kaput's model the use of symbols is a fundamental aspect, while in Kieran's model the use of symbols is not a prerequisite. For instance, Kieran's meta-level activities may be solved without using algebraic symbols at all. In this study, we will synthesize the two frameworks and propose a model that describes students' algebraic thinking in an explicit and parsimonious way. The synthesis of the two frameworks makes possible the combination of the salient parameters of each model to provide a comprehensive description of students' algebraic thinking. In addition, it provides a more accurate conceptualization of students' algebraic thinking by adopting the parameters of each model that are described in a more concrete way. For instance, transformational activities are implicitly integrated in the strands of Kaput's model, while in Kieran's model they are described as a separate type of algebraic activity. In the following section, we explain the rationale of including each parameter in the proposed model.

## **The Present Study**

The purpose of the present study was to propose and empirically validate a model describing Grade 9 students' algebraic thinking. In particular, the aims of the study were: (a) to propose a theoretical model describing the dimensions of 9<sup>th</sup> grade students' algebraic thinking based on a synthesis of the literature, (b) to examine the validity of the proposed model by using empirical data and (c) to examine the relations between the dimensions of algebraic thinking.

## **The Proposed Model**

The development of the proposed model describing students' algebraic thinking dimensions took into consideration Kaput's (2008) and Kieran's (2004) frameworks. To do so, we thought appropriate to include in the model the common types of thinking of each model and the parameters of each model that are involved to a greater extent in 9<sup>th</sup> grade algebra. Based on a synthesis of the literature, we hypothesized that 9<sup>th</sup> grade students' algebraic thinking consists of four distinct, but interrelated factors: (a) Generalized arithmetic, (b) Functional thinking, (c) Transformational ability, and (d) Modelling-meta-algebra. The dimension of generalized arithmetic is a common component of Kieran's (2004) and Kaput's (2008) models. Functional thinking is one of the main components of Kaput's model, while it is a sub-component of meta-algebra in Kieran's model. We included functional thinking as a separate component of the model because functions are a top priority topic in secondary school algebra. Transformational ability is a synthesis of transformational activities in Kieran's model and formalizations of Kaput's model and a fundamental type of activity in secondary school. Finally, the dimension of modelling-meta-algebra is a synthesis of components from both models. It includes Kieran's global, meta-level activities and Kaput's modelling dimension. In particular, it was hypothesized that generalized arithmetic involves applying algebraic thinking in arithmetical settings, by manipulating numbers and operations and exploring their properties, understanding the equal sign in numerical relations and becoming aware of the structure of arithmetic. Functional thinking refers to the identification and description of functional relationships between independent and dependent variables, by manipulating the concept of change and variation and generalizing patterns. Transformational ability refers to the transformation of numeric and algebraic expressions and solving equations by applying specific rules. Modelling-meta-algebra conceptualizes problem solving by using modelling, proving, manipulating variables in problem-solving situations and using symbols to represent situations.

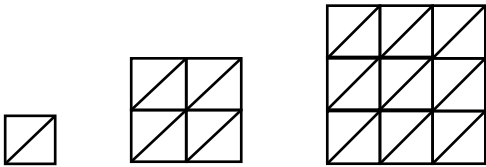

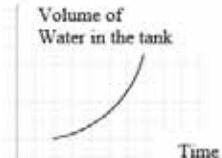

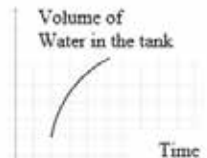

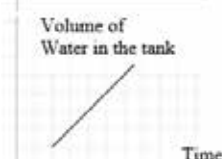

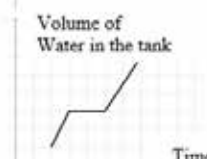

Type of Task	Example												
Patterns	<p>How many triangles are needed to construct the 10<sup>th</sup> figure?</p> 												
Relation between variables	<p>Which of the following equations corresponds to the relation of the variables in the table?</p> <div style="display: flex; justify-content: space-around;"> <div> <math>y=2x</math>  <math>y=x^2+1</math> </div> <div> <math>y=2x+1</math>  <math>y= x^2+x</math> </div> </div> <table border="1" style="float: right; margin-top: 10px;"> <thead> <tr> <th>x</th><th>y</th></tr> </thead> <tbody> <tr><td>0</td><td>1</td></tr> <tr><td>1</td><td>2</td></tr> <tr><td>2</td><td>5</td></tr> <tr><td>3</td><td>10</td></tr> <tr><td>4</td><td>17</td></tr> </tbody> </table>	x	y	0	1	1	2	2	5	3	10	4	17

Table 1: Functional Thinking Tasks

## Measures

The test items were adopted or developed based on previous research studies. The test items were evaluated by three experts in mathematics education who provided feedback on the content validity. The multiple choice tasks were corrected as correct or incorrect, while the open tasks were given partial marks for incomplete correct answers. Three types of tasks were used to measure the factor “generalized-arithmetic” (Kaput, 2008): (a) Properties and relationships of numbers and operations (Tasks 1-3), (b) Structure of numbers and numerical expressions (Tasks 4-6), and (c) Equality and inequality (Tasks 7-9). In Tasks 1-3 students had to use number and operation properties to calculate numerical expressions (e.g., find the result of  $-1245 \cdot 15 + 245 \cdot 15$ ). In Tasks 4-6 students had to treat numbers as placeholders and attending the structure of numbers rather than relying on computations (e.g., find the remainder of the division  $(946 + 950 + 952 + 960) \div 950$ , and examine whether the number  $3^{400}$  is divisible by 9). In Tasks 7-9 students explored equality and inequality situations (e.g., for what value of  $a$  is the inequality  $-10 > (-5)a$  valid). Three types of tasks

were used to measure the “transformational ability” factor: (a) Numerical transformations (Tasks 10-11), (b) Algebraic transformations (Tasks 12-13), and (c) Solving equations (Tasks 14-15). In Tasks 10 and 11 students had to make complex calculations with fractions and roots (e.g.,  $A = 2\sqrt{2} - 3\sqrt{3} + 7\sqrt{2} + 4\sqrt{3} + 5$ ). In tasks 12 and 13 students had to simplify algebraic expressions (e.g.,  $A = (a - 2b)(a + b) - (a + b)(a - a) + b(b + a)$ ). Finally, in Tasks 14 and 15 students had to solve fractional equations. Three types of tasks were used to measure functional thinking factor (see Table 1): (a) Finding the remote or general term of a pattern (Tasks 16-18), (b) Finding the relation between variables (Tasks 19-20), and (c) Finding the relation between variables in a graph (Tasks 21-22). Finally, we used two types of tasks to measure “modelling-meta-algebra” factor. In the modelling tasks (Tasks 23-25) students had to construct a mathematical model to solve a real-life problem, translate a word-situation to an algebraic expression using symbols and to represent a numerical relation using a bar-model (see Table 2). In the meta-algebra tasks (Tasks 26-27) students had to solve a complex problem involving inequalities and to make a proof (see Table 2).

Type of Task	Example																								
Modelling	<p>Which of the following corresponds to the relation: “One less than the double of a number is equal to five more than a second number”.</p> <div><div><table><tr><td>x</td><td>x</td><td>1</td></tr><tr><td>5</td><td colspan="2">y</td></tr></table><table><tr><td colspan="2">x</td><td>x</td></tr><tr><td>5</td><td>y</td><td>1</td></tr></table></div><div><table><tr><td colspan="2">x</td><td>y</td></tr><tr><td>5</td><td>x</td><td>1</td></tr></table><table><tr><td>y</td><td>y</td><td>1</td></tr><tr><td colspan="2">x</td><td>5</td></tr></table></div></div>	x	x	1	5	y		x		x	5	y	1	x		y	5	x	1	y	y	1	x		5

### Participants, Procedure and Data Analysis

One hundred fourteen 9<sup>th</sup> grade students (55 males and 59 females) were the subjects of the study from one private secondary school in Athens, Greece. The tasks of the study were randomly split into two parts. Each part was administered in the form of a written test during one school period. The two parts were administered in two successive weeks. The instructions were provided in written and verbal form. Confirmatory factor analysis was used to examine the validity of an a priori model, based on past evidence and theory. CFA was conducted by using MPLUS (Muthén & Muthén, 1998-2007). To evaluate model fit, three widely accepted fit indices were computed:  $\chi^2/df$  should be  $<2$ ; the Comparative Fit Index should be  $>.9$ ; and the root mean-square error of approximation (RMSEA) should be  $<.08$ . The Cronbach’s alpha index of internal consistency was very good ( $\alpha=.83$ ).

## Results

Confirmatory factor analysis (CFA) was used to evaluate the construct validity of the model; by validating that the a-priori model matched the data set of the present study and determined the “goodness of fit” of the hypothesized latent construct. The results of the study showed that the fit-indices were not satisfactory and the hypothesized model could not be supported ( $\chi^2/df > 2$ ,  $CFI < .95$ , και  $RMSEA = .08$ ). Examining the results of the study, we noticed that the correlation between functional thinking and modelling-meta-algebra factors was too high. Thus, we decided to examine the validity of an alternative model hypothesizing students’ variances in functional thinking and modelling-meta-algebra tasks compose a unified factor. Analysis showed that the fit-indices of the alternative model were excellent ( $\chi^2/df = 1.07$ ,  $CFI = .97$ , and  $RMSEA = .03$ ), validating empirically the fit of the structure of the alternative model to the empirical data. CFA showed that the factor loadings of the tasks employed in the present study were statistically significant and most of them were rather large (see Figure 1). The factor loadings ranged from .38 to .84, giving support to the assumption that all latent factors were adequately measured by the observed variables. Thus, in accordance with our theoretical assumption, all algebraic thinking measures were clustered into three first-order factors in the expected factor-loading pattern.

**Figure 1: The Algebraic Thinking Model**

Thus, analysis showed that algebraic thinking consists of three interrelated factors that is (a) generalized arithmetic, (b) transformational ability and (c) meta-algebra. The factor “meta-algebra” is a synthesis of students’ variances in functional thinking tasks, modelling and proving tasks. The correlations between the three factors were significant. In particular, the correlation between the factors “generalized arithmetic” and “transformational ability” was 0.78 ( $p < 0.05$ ), the correlation between “transformational ability” factor and “meta-algebra” factor was 0.60 ( $p < 0.05$ ) and the correlation between “generalized arithmetic” factor and “meta-algebra” factor was 0.76 ( $p < 0.05$ ).

To investigate the relations between the three algebraic thinking factors, we examined the fit to the data of alternative structural models, hypothesizing a direct sequential path between the three factors. The model that had the best fitting indices ( $\chi^2/df=1.04$ , CFI=.98, and RMSEA=.02) showed that “transformational ability” factor has a direct effect on “generalized arithmetic” factor and the latter predicts “meta-algebra” factor (see Figure 2). The regression coefficient of transformational ability factor on generalized arithmetic factor was 0.79 ( $p<0.05$ ), while the regression coefficient of generalized arithmetic on meta-algebra was 0.78 ( $p<0.05$ ).

**Figure 2: The Relation between Algebraic Arithmetic Factors**

## Discussion

The contribution of the study lies on the empirical evaluation of a proposed model that unpacks the dimensions of 9<sup>th</sup> grade students’ algebraic thinking. The results of the study showed that 9<sup>th</sup> grade students’ variances in algebraic situations might be modelled by three distinct and interrelated latent factors. The first factor involves students’ capacity in generalized arithmetic tasks, the second factor in transformational situations, while the third factor reflects students’ capacity in meta-algebra and functional tasks. The structure of the validated model is in line with the fundamental types of algebraic tasks suggested by Kieran (2004) and integrates ideas from Kaput’s model (2008). In particular, the validated model showed that meta-algebra factor is a synthesis of algebraic thinking parameters suggested by Kieran (2004) and Kaput (2008) and consists of functional thinking, modelling in various situations and proving. The inclusion of functional thinking in meta-algebra factor can be interpreted by the fact that in problem solving situations modelling activities prerequisite understanding the implied functional relations. Analysis showed that functional thinking can be described by adopting Kaput’s (2008) conceptualization that is generalization of patterns and manipulation of relations of variables in different representational forms. In conclusion, the empirically validated model that synthesized existing models in mathematics education could be a valid measurement model of 9<sup>th</sup> grade students’ algebraic thinking.

Analysis showed that there is a sequential effect between the three factors. Students’ capacity in transformational situations has a direct effect on their capacity in generalized arithmetic tasks and the latter affects directly meta-algebra. This is in line with research findings suggesting that modelling and meta-algebra tasks are the most difficult algebraic activities (Blanton et al, 2015). The finding that students’ capacity in transformational activities predicts generalized arithmetic might be explained by the fact that in 9<sup>th</sup> grade transformational tasks are mostly procedural and manipulating algebraic structures in a flexible way may help students conceptualize and express arithmetic structures in a generalized way more efficiently. Students’ advancement in transformational tasks might enhance their further development in generalized arithmetic by enhancing awareness of the structure of numeric and algebraic procedures, algebraic language and rules and applying generalizations strategically. Then, students’ advancement in generalized arithmetic might contribute in further enhancing their capacity in meta-algebra tasks, by developing generalization processes and

manipulating numbers and quantities relations strategically in different forms of representation. The aforementioned sequential relation might indicate a possible learning trajectory based on the fact that transformational ability and the ability to use algebraic language are essential so the students are successful in using algebraic structures for generalizing arithmetic tasks. Then students could succeed in meta-algebra that consists of more demanding tasks. Teachers should give students the opportunity to have systematic experience with transformational and generalized-arithmetic activities that lay the foundation to work with symbols and algebraic expressions that build up to an understanding of more abstract tasks. Moreover, teachers should take into consideration the aforementioned learning trajectory, which suggests a specific instructional sequence and the identification of key tasks designed to promote learning for each dimension of algebraic thinking. A future research could examine alternative learning trajectories in different populations and grades to get a further insight of students' difficulties and progression.

Generalization of patterns and regularities to describe functional relationships is a way for students to develop functional thinking, a core expectation in mathematics curriculum orientations (Blanton, Levi, Crites, & Dougherty, 2011; NCTM, 2000). Thus, it is important to provide students with opportunities to interpret variables and relations between variables, and to use co-variation and correspondence approaches to generalization. The promotion of functional thinking in primary school requires a specific preparation of prospective teachers (PTs), which in turn claims to assess their knowledge on the subject at the beginning of the teacher education programs they are attending. Taking this into account, a study was developed to analyze how Portuguese and Spanish PTs identify and express generalization in a task involving geometric patterns.

The data was collected through a questionnaire which included 6 tasks to evaluate relevant aspects of algebraic thinking. The questionnaire was applied to 94 Spanish and 70 Portuguese PTs attending the 1<sup>st</sup> year of a degree in primary education teaching, respectively at a public university in north of Spain and at two public schools of education in the center of Portugal. The PTs were not familiar with this kind of tasks and had received no instruction in algebraic thinking before the test. One of the tasks, that is focus on this poster, is a problem of generalization of a geometric growing pattern (linear) intending to assess PTs' functional thinking. Based on the first four terms of a pictorial sequence, made up of squares and indicating the number of vertices of each figure, the PTs are required to provide two possible strategies to find the number of vertices of a distant term of the sequence and to identify a generalization of the functional relation between the number of vertices and the number of squares of the figures of the sequence.

For a descriptive and interpretative analysis of the PTs' responses to this task, the following categories of strategies for obtaining distant terms and general rule were established (adapted from Barbosa, 2010): (1) *difference-recursive*: continues the sequence using the pattern or the numerical difference between consecutive terms (e.g. “with each new square we have to increase the number of vertices by 3”); (2) *difference-covariation*: uses the difference between consecutive terms as a multiplicative factor (e.g. “we add three more vertices in each step, so the general term for the number of vertices is  $4+3(n-1)$ , with  $n$  the number of squares”); (3) *multiplicative reasoning-missing value*: uses the rule of three to find distant terms (e.g. “if a figure with two squares has 7 vertices, then a figure with 25 squares has  $7 \times 25/2$ ”); (4) *multiplicative reasoning-proportional reasoning*: uses multiplicative strategies, starting from one known term of the sequence to find distant terms or a general rule (e.g. “the number of vertices is  $x$  times the number of squares”); and (5) *correspondence*: expresses a relation between the two varying quantities, based on the numerical

or pictorial sequence (e.g. “ $v=3n+1$  where  $v$  is the number of vertices, and  $n$  the number of squares”).

In the poster, we will present a complete analysis of the PTs’ strategies for obtaining distant terms and a general rule, providing a table with the percentage of PTs’ answers displaying each of the described strategies, both for Spanish and Portuguese contexts, as well as examples of those answers. Those results, in summary, indicate that in 62% of the Portuguese PTs’ answers they used a correct strategy to find a distant term of the sequence. In most of these cases they used a recursive strategy but also privileged the difference between consecutives terms as a multiplicative factor to obtain distant terms and the correspondence strategy. As expected, the PTs revealed more difficulties to find a generalization of a functional relation, since 50% of them did not answer and only 31% of their answers were correct. In these answers, they used difference-covariation and correspondence strategies. Almost half (48%) of their generalizations of a functional relation were based on a recursive strategy. However, in this case it resulted on incorrect generalizations.

Spanish results show that only 43% of the PTs’ answers were correct for computing the distant term, most of them based on a correspondence strategy. The recursive strategy was also quite frequent for obtaining distant terms (25%), although unlike in the case of Portugal, it led in most cases to incorrect results. One third of the Spanish PTs did not provide any answer to the question about generalization. Among those who did, correspondence and difference-recursive strategies were predominant, with only 20% of correct responses.

Moreover, it was seen that PTs of both countries adopted both visual and numerical approaches in the generalization of patterns, although they have privileged the former, and that, in general, they took into account the strategies used to find a distant term in the far generalization. However, the results related to the geometric pattern show important gaps in the algebraic reasoning of the PTs evaluated in both countries. These results provide information about the reasoning of PTs in tasks involving functional thinking and reveal the main difficulties they faced. In view of these results, possible considerations could be taken into account, like the benefits of including this type of tasks when designing courses of mathematical contents to help PTs develop their functional thinking.

### **Background to the Study**

Algebra has long been identified as an area of difficulty in the teaching and learning of mathematics. In Ireland such difficulties have traditionally been attributed to an over reliance on transformational-based activities when teaching the domain. These activities place a high emphasis on manipulating expressions and equations in a rote fashion, without a sound conceptual understanding of algebraic concepts. Bale (1999) describes conceptual understanding as an associative or connected body of knowledge, rather than a procedurally based knowledge, which can be applied to a variety of diverse contexts. To address this issue a reformed algebra strand was introduced to all post-primary schools in September 2011. In a shift from the transformational-based approach, the reformed strand followed the lead of several countries and advocated a functions-based approach to teaching the domain. This functions-based approach involves understanding the notion of change and making generalizations about how two or more varying quantities such as patterns of number sequences are related (Tanışlı, 2011). However, a study by Prendergast and Treacy (2018) found that not all teachers had successfully adopted the functions-based approach in their own teaching. As well as a reluctance to deviate from the transformational-based approach, teachers identified a lack of uniformity in the teaching and learning of algebra, particularly between primary and post-primary education. With such findings in mind, this study follows on from that research and focuses on teachers' insights into their teaching of algebra, particularly during the transition from primary to post-primary school. Data generated in this research specifically investigates upper primary and lower post-primary school teachers' conceptual understanding of algebra and, more particularly, linear equations.

### **Methodology**

The study was qualitative in nature and involved two phases of semi-structured interviews with a cohort of upper primary (10 – 12 years) and lower post-primary (12 – 15 years) school teachers. Participants were recruited through a purposive sample method from one local education authority in Ireland. The first phase of interviews took place in January 2018 and involved 15 teachers (9 primary [P1-P9] and 6 post-primary [S1-S6]) from 8 different schools (6 primary and 3 post

primary). The second phase of interviews took place in May 2018 and involved 13 of the same teachers from Phase 1 (8 primary and 5 post-primary). For the purpose of this submission, the authors investigate teachers' conceptual understanding of linear equations. This proposal focuses on one question asked of teachers in Phase 1 and the related follow up question posed in Phase 2:

**Phase 1 Question:** Take a look at the following equation:  $2x + 6 = 10$ . How would you typically explain to your students how to solve this equation?

**Phase 2 Question:** In the pre-interview, a number of teachers indicated that they would instruct their students to bring the six across the equals sign and it would change sign to become a minus. Are there any issues that you see with such an explanation? What changes (if any) would you make to the explanation?

## Preliminary Findings

Preliminary analysis conducted utilising the domain of expressions and equations as an organising framework (Bush & Karp, 2013), indicates a lack of conceptual understanding of linear equations on behalf of participating teachers and a prevailing over-reliance on 'rules without reason' when teaching algebra. For the Phase 1 Question, four out of the fifteen post-primary teachers effectively demonstrated conceptual knowledge of solving such a linear equation (S4: *So what I would start here is gain the notion of equality. Whatever we do to the left-hand side must be done to the right hand side*). Four of the primary teachers were either unable to generate a response or gave an inappropriate response (P5: *Let's see. Right well I would explain to them we need to find what  $x$  is... we haven't done these yet so...*). The other seven teachers' responses (five primary and two post-primary) were procedural in nature and all focused on the notion of numbers moving across the equals sign and then changing signs. (P1: *If it is a plus it becomes a minus and if it's a minus it becomes a plus*). The issue of moving across the equals sign and changing sign was probed further in Phase 2 and there were a variety of responses from the eleven teachers (8 primary and 5 post-primary). Three of the primary teachers did not see any issue with such an explanation (P6: *no I don't see anything wrong with it*). Four of the primary teachers could see where issues might arise but were unable to give an appropriate suggestion on how they would change the explanation (P2: *the biggest thing for me would be how is the  $+6$  changing to a  $-6$ ?*). While these findings are preliminary, the initial results raise concerns about participating teachers' conceptual understanding of algebra and, more specifically, linear equations. This research is intended to inform mathematics teacher education programmes in Ireland, particularly in the transition from primary to post-primary mathematics.

# Dealing with quantitative difference: A study with second graders

Margarida Rodrigues and Lurdes Serrazina

ESELx - Escola Superior de Educação, Instituto Politécnico de Lisboa, UIDEF, Instituto de Educação, Universidade de Lisboa, Portugal; [margaridar@eselx.ipl.pt](mailto:margaridar@eselx.ipl.pt), [lurdess@eselx.ipl.pt](mailto:lurdess@eselx.ipl.pt)

*The main goal of this paper is to understand students' reasoning when solving a task that involves quantitative difference. A qualitative methodology was used within the modality of teaching experiment. The data collection was done through the participant observation supported by video and audio recording of the work developed by two pairs of second graders, as well as the records of whole class discussions. To analyse data, we organized them into two categories: additive comparisons and complex additive relationships. The results show that these students were able to deal with quantitative difference, establishing relationships between quantities, even in a situation where initial numbers were unknown.*

*Keywords: Quantitative difference, quantitative additive reasoning, algebraic thinking.*

## Introduction

This paper reports part of the research developed by a project focused on flexible calculation and quantitative reasoning developed by teachers of the Higher Education Schools of Lisbon, Setúbal and Portalegre in Portugal. The main goal of the project is to build knowledge about the development of quantitative reasoning and calculation flexibility of students from 6 to 12 years old. The paper aims to understand second graders' reasoning when exploring and discussing a task that involves quantitative difference (Thompson, 1993). Specifically, the study aims to contribute to the knowledge of how early years students are capable of modelling situations focusing on their structures, abstracting from computation.

## Theoretical framework and empirical studies

Nowadays, algebra is viewed as a generalizing activity (Mason, 2008) with instruments that represent the generality of mathematical relationships, patterns, and rules. According to Kaput (2008), there are two essential aspects of algebraic thinking: (a) generalization and the expression of generalizations in increasingly systematic, conventional symbol systems, and (b) syntactically guided action on symbols within organized systems of symbols. The aspect (b) is developed later than aspect (a). These two aspects are embodied in three strands of algebra:

1. Algebra as the study of structures and systems abstracted from computations and relations, including those arising in arithmetic (algebra as generalized arithmetic) and in quantitative reasoning.
2. Algebra as the study of functions, relations, and joint variation.
3. Algebra as the application of a cluster of modeling languages both inside and outside of mathematics. (Kaput, 2008, p. 11)

The first strand is the primary route into algebra. In the early years, it is important to approach arithmetic focusing on number and operations properties or relationships, thus building generalizations from them. It is also fundamental to focus on mathematical processes (not on the final product), in order to put relationships and transformations as objects of study (Cusi & Malara, 2007).

Such an approach is conducive to the development of students' algebraic thinking. There is another approach within this first strand that is based on quantitative reasoning. This kind of reasoning is not based on the arithmetic of numbers but rather on quantities.

Quantitative reasoning is defined as an analysis of a situation into a network of quantities and quantitative relationships (Thompson, 1993). This kind of reasoning is related with the algebraic reasoning insofar as the focus is on the description and modelling of situations. It involves the relationships between quantities. As argued by Smith and Thompson (2008), situations involving complex additive relationships, that is to say, situations with more than three related quantities, could be fundamental for the development of students' quantitative reasoning. And this development prepares students for algebra in multiple ways. "If we want students to learn and use algebra as a sensible tool for expressing their thinking and solving problems, then work with complex problems must come first" (Smith & Thompson, 2008, p. 113). Quantitative reasoning has two roles: (i) to provide the content for algebraic expressions; and (ii) to support a flexible and general reasoning not necessarily relied on symbolic expressions (Smith & Thompson, 2008). Therefore, quantitative reasoning is foundational for both arithmetic and algebra, providing meaning and content for numerical and algebraic expressions.

There is a conceptual difference between quantity and number. According to Thompson (1993), "a person constitutes a quantity by conceiving of a quality of an object in such a way that he or she understands the possibility of measuring it" (p. 165). For instance, we can reason about the lengths of two objects and the amount by which one is longer than the other without having the numerical values of their measures. Furthermore, numerical difference is not synonymous with quantitative difference. Numerical difference is the result of subtracting, while quantitative difference is the excess found when one compares two quantities additively (Smith & Thompson, 2008; Thompson, 1993). For example, 9 is a numerical difference when we subtract 6 from 15 (doing a computation), and it is a quantitative difference when we compare the quantities 15 and 6, assuming it is the amount by which 15 exceeds of 6 or 6 falls short of 15. Besides this, we can reason about 9 as a quantitative difference without having absolute numbers, conceiving 9 as a relative change related to variables.

Several studies have reported results related with additive quantitative reasoning (e.g. Schliemann, 2015; Thompson, 1993). Schliemann (2015) referred to a study conducted through interviews with second graders and showed that they were able to understand that the equality of two quantities relative to concrete sets of objects, with known or unknown number of elements, remains after performing identical transformations in the two compared quantities. She also reported the results of longitudinal studies from third to fifth graders in USA about algebraic reasoning and function representations. In these studies, the verbal representation of functions emerged from the consideration of relationships between physical quantities and situations of daily life, and involved additive comparison. She concluded that the students, from the age of 8 years old, showed understanding of quantitative relationships which was fostered by the discussion on those functional relations. The students used informal strategies for solving early algebra problems. Examples of such problems are: to represent additive comparison in a situation of having physically two chocolate boxes with equal quantities but unknown absolute number and 3 more chocolates above one of the boxes; to represent additive operations as movements along a line marked with  $N-3$ ,  $N-2$ ,  $N-1$ ,  $N$ ,  $N+1$ ,  $N+2$ ,  $N+3$ ,  $N+4$ ,... to solve problems where initial value was unknown. The evaluation of the

intervention impact, at the end of 5th grade, demonstrated that the performance of the intervention group in the written test was significantly better in the items related to the intervention and similar to that of the control group in the other items. Another study, driven by a teaching experiment that involved 5th-grade students (Thompson, 1993), showed students' trouble with the distinction between the quantitative operation of comparing two quantities additively and the arithmetical operation of subtraction: they conceived a quantitative difference as an invariant numerical relationship. Thus, they assumed relative change as an absolute amount and needed to know absolute values before they could make comparisons. These studies allow us to compare the respective results with those of the study of our project. On the one hand, comparing results with second and third graders in similar early algebra problems but in more concrete conditions, and on the other hand, comparing results with fifth graders, looking at the difficulties or facilities in the performances of students of different grades in similar algebra problems. Hence, this confrontation allows a deeper understanding of the effective quantitative reasoning abilities of second graders, through the extension to progressively more abstract situations not based on arithmetic computation.

## Methodology

The project follows a qualitative approach framed in an interpretative paradigm (Bogdan & Biklen, 1994). It is focused on the educational processes and the meanings of the study's participants. It adopts the modality of teaching experiment conceived with the purpose to develop students' flexibility for calculation and quantitative reasoning. The Project team defined a sequence of nine tasks involving additive structure and discussed it with the classroom teacher.

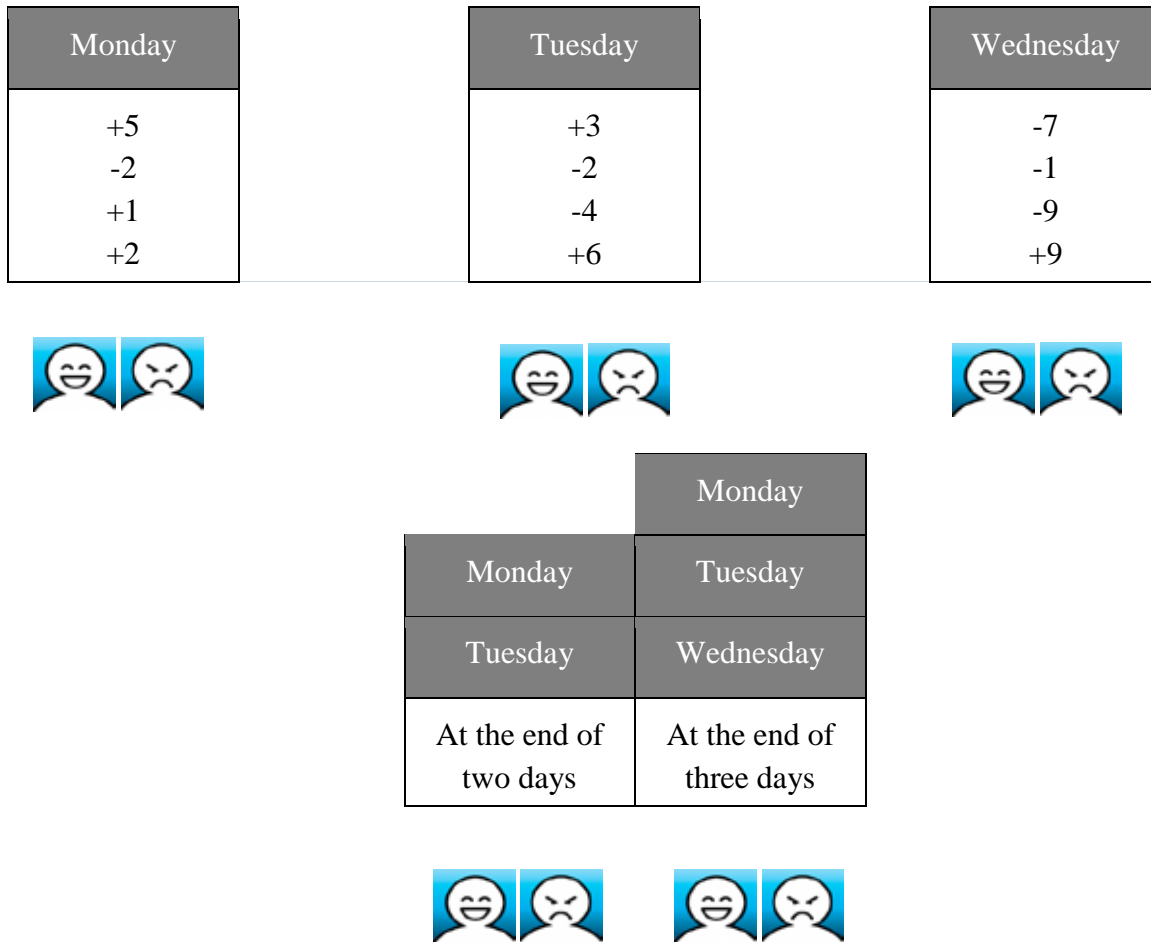

The task “*More? Or Less?*” was the fifth task in the sequence and was created by the Project team. It has a context of games with marbles and it was presented after another task that had the same context. It is composed by three parts. The first and the second parts are identical but the first one, besides involving different numbers, presents, in the middle, empty and white squares, while the second one presents black squares. The second part aimed to focus on quantitative difference corresponding to the excess found when gains and losses are compared. Figure 1 presents one example of each part.

**Figure 1: The first and second parts of the task**

The 3<sup>rd</sup> part aimed to focus on the balance between gains and losses and it does not present the absolute initial number of marbles (see Figure 2). At the end, students were asked to circle the face at the end of two days (Monday and Tuesday) and at the end of three days (Monday, Tuesday, and Wednesday). The students were requested to circle a smiley or a sad face depending on their sense of whether there were more gains or more losses at the end of the day(s). Besides this, the students were

expected to find the quantity representing how many marbles have been gained or lost at the end of the day(s), that is, the final quantitative difference. It should be noted, that they had not worked with notation of negative numbers before this task.

**Figure 2: The third part of the task**

The data reported in the current article were collected during two lessons of one hour and a half each that took place in the same class and they were conducted in the same way, within an exploratory teaching approach. The names of the students have been changed to ensure confidentiality. The data collection was done through the participant observation of the authors of this article, complemented with field notes and videotaping of the lessons. The students' productions were also collected. In the part of the exploration of the task, the videotaping focused on two pairs of students, Luís and Lúcia, and Paulo and João, selected because they habitually verbalized their reasoning among themselves.

The analysis focused on students' productions, field notes, video recordings and their transcriptions. To analyse data we defined categories built from the theoretical framework of Thompson (1993): (i) additive comparison; and (ii) complex additive relationship. The first one is illustrated for example by comparing 8 gains and 5 losses and determining 3 as the quantitative difference (there are 3 more gains than losses) or by comparing 6 gains and 10 losses and determining 4 as the quantitative difference (there are 4 more losses than gains). The second corresponds, for example, to the balance between several gains (+3, +4) and several losses (-8, -6) conceived as quantities without the necessity

of having the absolute number of marbles in situations with more than three related quantities: at the end, the quantitative difference is -7.

## Results

During the first lesson, the pair Luís and Lucía explored the first and second parts of the task in a consecutive manner, prior to the discussion of the first part. Luís asked: "Why is it here black?". Although informed that they should write nothing there, Luís wrote the various results within the black squares, despite Lucia's reaction ("We cannot!"), thus addressing the second part in the same way as the first one. To do the calculations, they used compensation strategies, adding first 10. For example, for calculating  $12+8$ , they did:  $12+10=22$ ;  $22-2=20$ . Also the pair Paulo and João performed all the calculations, as in the first part.

In the whole class discussion, the teacher asked different pairs to go to the blackboard to present their solutions for the first part of the task.

Nádia: Here is 15. Then we added another 8 that gives 23. Minus 5 gives 18.

Teacher: Yes? ... So how did you find the bottom one?

Nádia: Because here (*pointing to 15*) to reach the 18 is 3 more.

Teacher: So the first and the last were enough; the jumps above do not matter?

*Maria hesitates.*

Teacher: I want to know if the jumps above also help.

Paulo: Yes, they help.

Teacher: Why?

Paulo: (*goes to the blackboard*) Because if from 8 you take out 5, you get only 3 from here (*points to the bottom square*). And knowing that only 3 were missing, here from the first to reach the last we only needed 3 more. For the last.

Teacher: So did they gain or lose?

Guilherme: They gained because they got 3 more.

The students were able to focus on the balance between gains and losses of marbles, rather than on numerical calculations with the help of the teacher's questioning. The classroom discourse was centered on quantitative difference ("3 more") instead of absolute number of marbles (15 and 18).

During the second lesson, the teacher gave the second part of the task. Since Luís and Lúcia had already done it in the previous lesson, the teacher asked them to talk to each other about how they had done it. When the teacher approached the pair, she asked:

Teacher: Do you need this middle square?

Luís and Lúcia: No.

Teacher: Tell me another way to reach this without saying the number in the middle. If it's painted of black, maybe it would not be necessary.

Luís: 8 minus 5 gives 3 (*pointing to the arrows*).

- Teacher: Gains or losses?
- Luís: Gains. 3 more.
- Teacher: And here? (*pointing to the situation below*)
- Luís:  $15 + 9...$
- Teacher: But is the middle square necessary?
- Luís: Plus 9, minus 10.
- Teacher: Okay. (*the teacher moves away*)

Luís erased the numbers written in the black squares, indicating that he followed the teacher's guidance that these numbers would not be necessary. Luís seemed to be able to focus on quantitative difference between gains and losses in both games, as encouraged by the teacher. However, in the other situation, he began verbalizing the numerical computations and just after the teacher's intervention, he focused on quantitative difference resulting from *additive comparison* ("Plus 9, minus 10").

With regard to the other pair, Paulo showed the ability to focus on the balance between gains and losses. He decided to invent two other situations, asking João to determine the jumps. When the researcher got closer, Paulo explained the "-6+4" situation: "It's 6 minus 4. It's going to give a negative number". Probably Paulo used a vocabulary from his home context since the teacher had not used this expression in classroom in the previous lessons.

At the moment of whole class discussion, the teacher asked:

- Teacher: Why do you think the square is painted of black?
- Student: It's to guess the number and keep it in our head.
- Teacher: Does it make sense?
- Gil: To not write.
- Maria: To help us think.
- Paulo: The square is painted because the number under that square should not interest.
- Teacher: So how does it solve?
- Luís: It's  $+8-5$  that gives  $+3$ .
- Teacher: Gained or lost, Gil?
- Gil: Gained  $+3$ .
- Teacher: Without looking to the jumps, how can we see if he gained?
- Students: We see in the numbers, from 12 to 15.

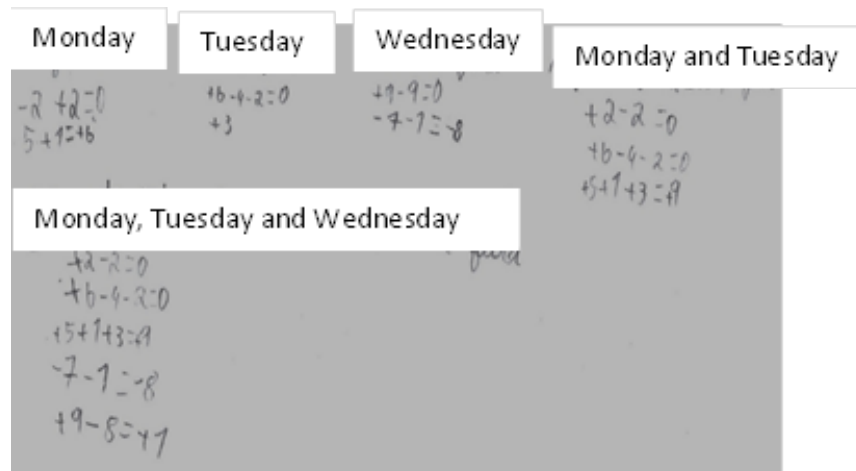

With the help of the teacher's guidance, the students were able to relate the balance between gains and losses with the quantitative difference between 15 and 12 ("It's  $+8-5$  that gives  $+3$ "; "Gained  $+3$ "; "We see in the numbers, from 12 to 15"). Then the teacher introduced the third part of the task:

- Teacher: What if there were no numbers neither at the beginning nor at the end?

Luís: It's just to find out if you gain or lose and how much.

Teacher: This new proposal has only the gains and losses in different games. Let's see what happens at the end of each day.

Paulo seemed to deal easily with quantitative difference whether it is an excess or a deficit. He did this part very quickly, in two minutes. When the researcher got closer, Paulo explained: "these annul each other" (for example,  $-2, +2$ ), having calculated only the remaining ones. His solution presents positive and negative numbers notation (with the signals  $+$  and  $-$ ) and it can be seen in Figure 3.

**Figure 3: Paulo's resolution of the third part of the task**

The pair Luís and Lúcia approached the third part using a different strategy. They added the gains, added the losses, and then did the additive comparison. In the Wednesday's situation, the students surrounded the sad face, understanding that at the end of the day, the player lost 8 marbles. They registered " $-17; +9$ " and " $-8$ " below the sad face.

In the whole class discussion, the most presented strategy was the one used by Luís and Lúcia: to add the gains and the losses, and then determine the quantitative difference. For example, for Tuesday, the pair Marta and Monica quickly recorded on the blackboard " $+9 - 6 = +3$ " and drew a 'smile'. The students concluded: "The difference between 9 and 6 is 3 to gain".

Teacher: Is there another explanation?

Paulo: Yes, the  $+6, -4$  and  $-2$  annul themselves. (*The teacher records on blackboard:  $+6 - 4 - 2 = 0$* )

Paulo: And only  $+3$  left over.

This idea of 'annulling' was used by other students in situations that followed and many of them used it correctly.

## Conclusion

The students were able to focus on difference as a quantitative structure, looking at gains and losses. Thus, on the contrary to what happened with fifth-grade students in the study of Thompson (1993), these second graders were able to conceive a quantitative difference independently of numerical information about quantities (Smith & Thompson, 2008); they did not need to know the initial number of marbles, in the third part of the task, to be able to think about gains and losses. These students were

able to focus on quantities, building relationships from them as stated by Cusi and Malara (2007) and as happened in the studies reported by Schliemann (2015). Hence, they conceived difference as a relative change independently of actual values, considering them as variables within a relational dimension.

This study stresses the fundamental importance of modeling the situations, revealing their structure. Both structural and relational dimensions are key elements of algebraic thinking. The results highlight the easy way in which students manipulated the quantitative differences attributing a contextual meaning, and also suggest the potential of a work focused on quantitative relationships to enhance early algebraic thinking. They open new lines for research in order to understand the multiple factors that may influence students' learning, namely the role of task design, in particular the black square and the final part with unknown initial numbers, as well as the role of teacher's questioning, in particular the funneling questioning, in the development of students' quantitative reasoning.

## Short note on algebraic notations: First encounter with letter variables in primary school

Anna Susanne Steinweg

University of Bamberg, Germany; [anna.steinweg@uni-bamberg.de](mailto:anna.steinweg@uni-bamberg.de)

*Algebraic thinking often requires generalisation processes. Generalisations of patterns are one frequently used design in early algebra settings in research and practise. Symbolical letter variables are not common in primary school and actually not needed by the children to articulate their pattern generalisations. Nevertheless, from a research perspective it is interesting to explore children's spontaneous interpretations of letter notations. The reactions of 3<sup>rd</sup>-and 4<sup>th</sup>-graders, who participated in an explorative study presented here, might provide a starting point to sensible appreciate the individual thoughts and ideas about letter variables in further studies.*

*Keywords: Early algebra, generalisation, symbolic notations, variables.*

### Introduction

Algebraic thinking in all its possible facets are described in detail in several studies (Kieran, 2018). One of the major aspects of algebraic thinking –especially in early algebra– is generalising from given cases to rules and description of the patterns found. Symbolical notations in letter variables can condense these rules in algebra lessons in secondary schools.

In some research approaches, based on the so-called Elkonin-Davydov curriculum, algebraic thinking is assumed as equal to using letter notations (Dougherty & Simon, 2014; Dougherty, 2008; Freudenthal, 1974). Others follow the way to re-invent algebra by the children (Amerom, 2002). Nowadays, almost everyone involved in early algebra research might agree on the fact that the children will not invent letter notations on their own.

Teachers need to introduce unfamiliar terms, representations, and techniques, despite the irony that in the beginning students will not understand such things as they were intended. The initial awkwardness vis-à-vis new representations should gradually dissipate, especially if teachers listen to student's interpretation and provide students with opportunities to expand and adjust their understandings. (Carragher, Schliemann, & Schwartz, 2008, p. 237)

Notation in letter variables does not emerge. It also holds true that letter notation is not needed to adequately describe patterns found (Akinwunmi, 2012). However, a suitable verbal description of complex patterns is sometimes tough to find. Letter notation is therefore a useful condensation and last not least a cultural heritage or an aspect of enculturation: "Enculturation into a mathematical expectation" (Mason, Stephens & Watson, 2009, p. 14). The study described here aims to receive an impression of primary children's initial interpretations of a vis-à-vis confrontation with letter notations, and listen to these ideas. The findings might base teaching advices and further research.

### Theoretical framework

Letter notations use variables. Variables have at least three different aspects and features. They can

- represent quantities (Kieran, 2004) as an unknown (Strømskag, 2015; Freudenthal, 1983) in an equation like  $5+x=8$ ,

- express rules of numerical relationships (Kieran, 2004) like in  $a+b=b+a$ , which Strømskag (2015) identifies as parameters and Freudenthal (1983) as indeterminate,
- express generality arising from patterns (Kieran, 2004) as variables (Strømskag, 2015; Freudenthal, 1983) like  $n \otimes 2n+2$  (cf. Figure 1), which are the main focus in the study presented in this paper.

**Figure 1: Pattern Sequence  $n \otimes 2n+2$**

Working on pattern sequences, like the one given in Figure 1, allows at least four different approaches, which can be summarised in the ReCoDE (Recognise-Continue-Describe-Explain) model (Steinweg, 2014). As mentioned above early algebraic thinking deeply depends on generalisations. A typical task implicitly challenges the children to generalise already whilst recognising the regularities: “Generalizing starts when you sense an underlying pattern, even if you cannot articulate it” (Mason, Burton, & Stacey, 2010, p. 8). Nevertheless, the articulation or even notation is a substantial element in the development of algebraic abilities. Experienced learners may use variables to articulate and to communicate findings with others in describe- or explain- phases.

When students perform a pattern generalization, it basically involves mutually coordinating their perceptual and symbolic inferential abilities so that they are able to construct and justify a plausible and algebraically useful structure that could be conveyed in the form of a direct formula. (Rivera, 2010, p. 298)

Dörfler (2006) regards notation as mathematical object itself, through which mathematical learning can be initiated. In any case letter notation has to be interpreted by the learner. This, of course, is the fact for every mathematical object like digits and operations signs. In line with Steinbring (2015) one has to keep in mind, that “the elements of the mathematical world cannot be perceived directly by our senses but consist of ‘invisible structures’ and relations” (p. 292). Hence, mathematical thinking depends on working on mental objects:

I speak of the constitution of mental objects, which in my view precedes concept attainment and which can be highly effective even if it is not followed by concept attainment (...) The fact that manipulating mental objects precedes making concepts explicit seems to me more important than the division of representations into enactive, iconic, and symbolic. (Freudenthal, 1983, p. 33)

The need for individual interpretation of mathematical objects and operations by images and explanatory models is fundamental for mathematical learning (Hofe & Blum, 2016). The interpretation of letters as notation of variables is nothing else than this usual habit. Rivera (2013) identifies the guessing of a rule of a given figural pattern as abductions and therefore as a fundamental mathematical activity. Of course ‘symbol sense’ is crucial for algebra because it allows

to see algebra as a tool for understanding, expressing and communicating generalizations, for revealing structure, and for establishing connections and formulating mathematical arguments (proofs). (Arcavi, 1994, S. 24).

In the study presented here pattern sequences as “arbitrary patterns” (Strømskag, 2015, p. 475) and no figurate numbers (e.g. square numbers) are used. The given pattern in predefined coloured dots

expects the learners to see a double structure or “a regularity that involves the linkage of two different structures: one spatial and the other numerical” (Radford, 2011, p. 19). In an explicit notation of the underlying rule the commonly used letter (n) corresponds with the position (ordinal) of the figure in the pattern as a whole. The cardinal amount of black and white dots needs to be set in relation to this ordinal number. The explicit formula represents in a direct approach “a functional relationship between position and numerical value of an element” (Strømskag, 2015, p. 475). As mentioned earlier the letter notation is in a way independent from generalising the pattern:

The difference between finding rules and expressing those rules in formal notation highlights a difference I see between these two aspects of mathematics. Spotting patterns and finding rules is algebraic in nature whereas how to express those rules is a matter of language and notation. (Hewitt, 2009, p. 43)

Thus, Hewitt (2012) differentiates between the necessary and the arbitrary in algebraic notations. The notation of spotted regularities also depends on (school) experiences (Radford, 2002). The didactical dilemma is, that “notation is not an afterthought, but rather an inherent part of mathematical activity” (Hewitt, 2016, p. 168).

Some pitfalls of educational approaches to letter notations are well documented. If tasks and learning-teaching-environments encourage pupils to match letters to word beginnings as abbreviation of names for objects in context situations (so-called fruit-salad-algebra (Thomas & Tall, 2001), or positions in the alphabet, these ideas hinder a deeper understanding of algebraic variables: “This ‘letter-as-object’ misconception can haunt students in their efforts to set up equations throughout their algebra careers” (Arcavi, Drijvers, & Stacey, 2017, p. 52).

A recent teaching-experiment study in two first grade classes worked on functional relations in context problems (Blanton et al. 2017). The findings indicate levels of understanding and make clear, that the letters are sometimes viewed as representing the context objects. The context situation therefore might hinder an interpretation of letters as mathematical object. Nevertheless, children in primary school of course need something to refer to while making sense of letter variables. The mediator chosen in this study is dots and dot pattern sequences.

The German situation concerning algebraic thinking is very special because algebra is not a curricular content (Steinweg, Akinwunmi, & Lenz, 2018). Patterns are mentioned in the syllabi and are therefore suitable for German primary school children, even though pattern sequences (like Fig. 1) are not frequently used. The study here tries to figure out the reactions to letter variables of German pupils with –under these conditions assumed– minor or none prior algebraic knowledge and whether the findings on children’s understanding of letters correspond to international findings:

- *What kind of spontaneous interpretations of letter notations of a pattern sequence ( $n \in \mathbb{N}$ ) can be categorised?*
- *Does the age of the pupils or the pattern sequence given effect the interpretations?*
- *Are there any correlations between continuing the sequence, finding the 100<sup>th</sup> figure, and the ability to interpret the letter notation?*

## Methodology and Design

The study is an explorative one-shot written test design with no teaching experiments. Five mixed-age classes 3<sup>rd</sup>- and 4<sup>th</sup>-grader (8 to 10-year-olds) and in total 96 children participated in the study.

The designed written test uses three different versions, each focusing on one pattern sequence ( $n \oplus 2n+2$ ,  $n \oplus 2n+1$ , and  $n \oplus 3+n$ ) in order to allow each child an independent reaction to the task in the classroom setting. Each test version is therefore worked on by 32 children.

Each test version includes only three tasks on one sheet of paper. The first two tasks are placed on the top half of the sheet, the third on the bottom half. The task sheet was folded in the middle, so that the children only see the first two tasks. They are permitted to unfold the sheet only after working on these two tasks.

Each child gets one of the pattern sequences and is asked to draw the next figure (like in Figure 1). The second task asks to describe how to find the 100<sup>th</sup> figure in this sequence. After unfolding the tasks sheet the third task appears. It is a confrontation with one possible algebraic letter notation for the given relation (example Figure 2). This task invites the child to think about this unfamiliar symbolic letter description and to comment on it. The reactions might reveal mental images the children use.

Adults describe the pattern like this:  $2 \cdot n + 2$   
Does this fit? What do you think?

**Figure 2: Confrontation-task with the algebraic letter notation**

The design follows the idea to embed the confrontation with the letter notation in a useful way in a purposeful task. Purposeful is meant here against the background of the definition by Ainley, Bills and Wilson (2003) alongside with utility which is understood as “knowing how, when and why that idea is useful” (p. 2). It is hoped for that the learner sees the connection of the letter symbols after working on the pattern individually. The letter notation, at best, condenses the idea of generalisation of the pattern the child already used in the 2<sup>nd</sup> task (100<sup>th</sup> figure in the pattern).

<div> <div>Ja!!</div> <div>Yes!!</div> </div> <div>statement</div>		<div> <div>Wißt kh nicht</div> <div>I don't know</div> </div> <div>none</div>

fully			

**Figure 3: Categories and examples of reactions of the algebraic notation  $2n+2$**

The answers to the first two tasks are analysed in a common way. The continuations are categorised in *none*, *individual*, *correct without coloration*, and *correct*. The description of the 100<sup>th</sup> figure in the pattern are categorised in *none*, *individual*, *initial approaches*, and *correct*. The reactions to the letter notation are the main focus of the study. Here a wide range of answers are found (Figure 3). The

categories *none*, *individual*, *partly*, and *fully* are suitable. Additionally, the category *statement* is needed, because the task allows yes-or-no-answers, which are frequently used.

## Findings and Discussion

### Quantitative Results

78 % of the children are able to continue the pattern *correctly* and over one third (35 %) describes the 100<sup>th</sup> figure *correctly*. Taking into account that pattern tasks –not even on Recognise-Continue-Describe level– are not common in German primary schools, these results are quite pleasing.

The duration of schooling of the participating children differs between just started the 3<sup>rd</sup> year or rather 4<sup>th</sup> year. This might have an effect on the reactions. Although, it should be mentioned again, pattern tasks are not frequently used in German mathematics lessons. At first sight it seems like 4<sup>th</sup>-grades are getting better, because the numbers of *no answers* are dropping (Table 1). But it may only be the case that the older the children the more cheeky or assertive they are, because the number of *statements* increases inversely.

Table 1: Impact of duration of schooling

Table 2: Impact of the pattern

Furthermore, an impact of the given pattern, illustrated in Table 2, is visible. The number of *full* interpretations of the pattern  $n \oplus 2n+1$  is considerably higher than the others. Simultaneously the number of *no answers* is the largest as well. The  $n \oplus 3+n$  pattern triggers the most *partly* interpretations and the highest number of *statements*.

Table 3: Bivariate analysis interpretation of letter notation and finding the 100<sup>th</sup> figure

Additionally, correlations between the reactions to the first two tasks and the ability to interpret the formula are proved. It can be shown that the ability to continue the pattern *correctly* is necessary but not sufficient for a suitable interpretation. This means, every child who gives a *full* interpretation of the letter notation continued the pattern *correctly*, but not every child who correctly continued the pattern sequence is able to interpret the symbolical letter notation. Moreover, correlations between

the experiences and reactions to the generalising task before (100<sup>th</sup> figure in the pattern) and the interpretation of the letter notation could be expected –particularly with regard to the focus on generalising in various research studies in early algebra. The bivariate analysis (Table 3) indicates that –although the number of children who are able to read the letter notation *fully* is quite small– it is striking that 9% of them have no clue how to find the 100<sup>th</sup> figure in the pattern sequence. Regarding the *partly*-readers of the letter notation, the amount of children who have not mastered a suitable 100<sup>th</sup> figure grows up to 51%. Apart from that, 52% of the children who give *individual* interpretations of the letter notation have found the 100<sup>th</sup> figure in the pattern sequence beforehand. The expected causal relation –that generalising the pattern by finding the 100<sup>th</sup> figure in the sequence directly influences the ability to interpret the letter notation– therefore cannot be confirmed in this study.

### Qualitative Findings

The reactions of the children categorised as *individual* or *partly* are of great interest to understand children's first-encounter-interpretations of letter variables of relations in  $\mathbb{N}$  ( $n \otimes kn + t$ ). One striking aspect is, that none of the *partly* interpretations refer to the multiplicative part of the term ( $kn$ ) but in each case the additional part (constant element  $t$ ) is described (a typical example is given in Figure 3). A recursive idea is read into the explicit letter notation by two other children. One of these children explicitly specifies +2 as the two dots increase from pattern to pattern and does not assign the painted dots (constant element) to +2.

The *individual* reactions try to assign an individual meaning to the given letter. Some regard the variable as an unknown, which has a certain value like 2 (Figure 3). Five children strongly suggest changing the  $n$  to an  $h$ , because it means 100 in their eyes. This might be a result triggered by the second task, which asks for the 100<sup>th</sup> figure of the pattern. Two others match  $n$  to 14, because  $n$  is the 14<sup>th</sup> letter in the alphabet. One child expects  $n$  to equal nine, because nine ('Neun') starts with an  $N$ . These interpretations are of special interest against the background of fruit-salad-algebra (Thomas & Tall, 2001) and 'letter-as-object' misconception (Arcavi, Drijvers, & Stacey, 2017).

### Closing Remarks

The study presented here is limited, because research about the importance of "perceptual diversity" (Rivera, 2013, p. 5), the possibility of different colouring, and various individual interpretations of possible structures (Twohill, 2018) are not taken up in the design. The tasks only involve one predefined explicit formula at a time and recursive thinking is somewhat ignored – even though two children stick to their recursive approach anyway. This small study can only be seen as a starting point for verifying or falsifying the results. In summary, the striking findings are:

- The impact of the pattern used in the tasks is noticeable but not coherent.
- Age and duration of schooling might have an effect.
- The ability to continue patterns is necessary but not sufficient for the interpretation of letter notations (symbolic terms).
- The ability to generalise patterns (find the 100<sup>th</sup> one) seems not necessarily engender (sound) formula interpretations.

Especially the latter result requests further studies. These studies are thinkable in two ways: Larger studies to proof possible correlations or smaller study with a focus on interviews and qualitative

analysis. Some interviews in different age-groups are carried out currently. The deeper inside in children's thoughts while interpreting the letter-symbols will be most interesting.

# Structures identified by second graders in a teaching experiment in a functional approach to early algebra

María D. Torres, María C. Cañadas and Antonio Moreno

University of Granada, Faculty of Education, Spain; mtorresg@ugr.es, mconsu@ugr.es, amorenoverdejo@gmail.com

*We describe structures and generalisation in four second graders (7- to 8-year-old) at the beginning and end of a classroom teaching experiment involving an early algebra-related functional context. No significant differences were found in their ability to identify structures and generalise at the beginning and at the end of the teaching experiment. All the identified structures in the questions involving specific cases and all the students generalised when they were explicitly prompted.*

*Keywords: Functional thinking, structures, generalisation, teaching experiment.*

## Background and conceptual framework

Traditionally, algebra is not introduced until secondary school in most countries, Spain is one example (Ministerio de Educación Cultura y Deporte, 2014<sup>1</sup>). That approach has induced failure in many students who react to the difficulties encountered by rejecting algebra and mathematics in general (Kieran, 2004). In early algebra the discipline is introduced in the first few years of schooling by working, among others, with the generalisation of functional relationships, known as the functional approach to early algebra. Children and adults both generalise by identifying regularity in inter-variable relationships. Notions such as generalisation and the structures in functional relationships are key elements in the study of students' functional thinking (Twohill, 2018). This paper addresses second-year primary school students' ability to identify structures and generalise in a functional approach to early algebra.

Functional thinking, as an approach to introduce algebra in the early grades, involves the relationship between two or more variables, and is based on the construction, description and representation about functions and their constituent elements (Cañadas & Molina, 2016). Patterns and regularities are of significant importance in the study of such thinking, for they interrelate the variables in a situation. Earlier studies reported that primary school students of different ages with no specific prior training were able to perform tasks involving functional thinking (Blanton, Brizuela, Gardiner, Sawrey and Newman-Owens, 2017). The notion of structure acquires different meanings in early algebra (Molina & Cañadas, 2018). In the functional approach, it is associated with how inter-variable regularity is organised, which pupils may represent in different ways when working with specific values as well as when generalising the relationship between variables (Pinto & Cañadas, 2017a). Structures can be semantically equivalent. For example, in algebraic symbolism,  $x + 4$ ,  $x + 2 + 2$  and  $x + 1 + 1 + 1 + 1$  are equivalent expressions (equivalent semantic structures) because these expressions are the same thing through arithmetic computations, but their external structure is different.

Limited studies have addressed these notions in primary education students. Pinto and Cañadas (2017a, 2017b), in research on structures and generalisation in third and fifth-year students, described differences in the amount and variety of the structures identified, both of which were greater among

---

<sup>1</sup> Ministry of Culture, Education and Sports of Spain.

the younger children. Third-year students tended to work with specific cases while those in fifth-year were able to establish generalizations; most of them generalised structures and used the same structure for both specific situations and the general case and their answers were more coherent. Three of the fifth-year students generalised in tasks involving specific cases. The authors also distinguished two types of generalisation: spontaneous (when students generalised in tasks describing specific situations) and prompted (when they generalised when asked to do so in connection with the general case). Tasks or worksheets were designed assuming that generalisation would arise in a later stage, so these students evidenced prompted generalisation (Pinto & Cañadas, 2017a). Generalisation and structure are not independent notions. Identifying structure, whether through specific or general situations, is requisite to generalising. We take generalising to mean seeing general patterns in specific situations (Mason, 1996). The inductive model proposed by Cañadas and Castro (2007) was implemented here to foster this kind of abstraction. At the outset, we used specific situations (variables with specific values), aiming to prompt generalisation (of the functional relationship) through the detection of regularities. Structures and generalisation may be represented in different ways by primary school pupils: natural language, algebraic symbolism, tables or graphs (Radford, 2018). The present study explored the identification of structures and generalisation in second year primary school students at the beginning and at the end of a teaching experiment involving functional thinking.

## **Method**

In this paper, we focus on part of a broader teaching experiment (Steffe & Thompson, 2000), about functional thinking in second grades (7-8 years old). We present different problems during the five sessions of the teaching experiment and the two interviews. Three of the purposes of the teaching experiment were to: (a) explore how students relate the variables involved; b) identify structures on students' responses; (c) explore students' generalization process. This paper analyses the information gathered in two interviews: one held after the first session and the second after all the sessions were completed. The data were analysed to ascertain differences between the first and second interviews in terms of the structures identified and generalisation expressed by students.

## **Participants**

The subjects were four 7- to 8-year-old, second graders from a Spanish school. They had not been previously exposed to generalisation tasks involving linear functions. Their prior knowledge included the numbers from 0 to 399, addition with carrying and subtraction with borrowing. After the first session of the teaching experiment, in which a worksheet was administered to the entire class (24 pupils), the students were classified into two groups (intermediate and advanced). Students in advanced group generalized the functional relationship; students in intermediate group did not generalize. Four students, two from each group, were selected for the interviews. The subjects selected in each group were chosen by the classroom teacher considering that they should be participative.

## **Information gathering instrument**

The five classroom sessions conducted were video-recorded. In each session we posed one or two tasks in different contexts involving different functions. Each task was described on a separate

worksheet. Two semi-structured individual interviews were held with the four students selected, one after the first session and the other after the last.

### Classroom sessions

A contextualized task involving a linear function was posed in each session. In all sessions, students first worked with specific cases of the function from which, after identifying the structure, they could pose new specific cases or generalise. Some of the tasks were original and others taken from the studies cited in section 1 above. The context and function addressed in each session are listed in Table 1. We first involved an additive structure (it is supposed to be easier following previous studies) and then we combined the additive and multiplicative structures. We observed that the students had more difficulties to reach the generalization in the later, so we involved only multiplicative structure. We selected contexts close to the students' experiences according to the students' teacher. The objective of each session was to explore students' generalization within different contexts.

Context	Functional relationship
<b>Session 1:</b> ball dispenser <b>Session 2:</b> amusement park 1	$y = x+3$
<b>Session 3:</b> amusement park 2	$y = 2x+1$
<b>Session 4:</b> birthday <b>Session 5:</b> train stations	$y = 2x$

**Table 1: Characteristics of session tasks**

The dynamics were the same throughout the experiment. Three members of the research team were present in the classroom: the teacher-researcher (he was not the usual teacher), a support researcher and a researcher who video-recorded the session. Each session was divided into several parts: first we explained the task to the whole class, then we distributed the session-specific worksheets and lastly the task was discussed by the group as a whole. The students received no feedback on their replies. The worksheet used in the first session is described below as example and because the interviewees were selected on the grounds of their performance in that session.

### Session 1 worksheet

The session 1 worksheet contained five questions about a ball dispenser that when fed balls returned a certain number further to the functional relationship  $f(x) = x+3$ . We introduced the context to the students as follows: “we have a machine in which we introduce and leave balls”. Four questions involving specific cases were posed as shown in Figure 1. We organized the balls in such a way that did not facilitate the structures identification through visualization.

**Figure 1. Specific case question**

The last question, involving generalisation, is shown in Figure 2.

Now we're going to play a game. The winner has to figure out how the machine works. How can you tell how many balls will come out?

**Figure 2. General case question**

This worksheet helped to classify the students into two groups based on their answers: intermediate and advanced. The first group included students who had identified regularity in several of the questions and the other students who were able to generalise. The classroom teacher then chose two students from each category (intermediate, S2, S1; advanced, S4, S3). Hereafter, the students are identified by the letter S and a randomised number for anonymity purposes.

### Interviews

We designed two semi-structured interviews, each with a different protocol. Two tasks involving additive linear functions were designed for each interview. In the first the context was the same as in session 1 ( $y = x + 3$ ). In the second interview the context was the age of two superheroes, one 4 years older than the other ( $y = x + 4$ ). The structure was the same in the two interviews: We began with specific, non-consecutive (to avoid recursive patterning in students' answers) situations and progressed inductively toward generalisation. The design of the second interview, which built on the first, also involved an addition function to ensure inter-sessional comparability of the students' replies. The guides for the two interviews were analogous. The guide for the second interview is presented in Figure 3. We note that in the last question about generalization, letters were random values that served to express examples, the question did not involve or asked for symbolic letters.

#### 1. Exploration of specific cases

- Identify the functional relationship
- Apply the functional rule in different specific cases
  1. Specific cases
    - When Iron Man was 5 years old, Captain America was 9.
    - When Iron Man was 7 years old, Captain America was 11.
    - When Iron Man was 3 years old, Captain America was 7.
  2. Specific cases proposed by the student
    - Give me an age for Iron Man (\_\_\_). If he's that old, how old is Captain America?

#### 2. Generalisation

- Express the generalisation
  - How would you explain to a friend what she has to do to figure out Captain America's age?
- Reason with the generalisation
  - One of your classmates said that 'When Iron Man is XX, Captain America is YY'. Do you agree?

**Figure 3. Protocol for the second interview**

## Data analysis

The data gathered during the two interviews were analysed with a system of categories based on the structures identified by the students in both specific and general cases. Students were considered to have identified a structure when they answered two or more questions referred to the same task with the same regularity or generalised a regularity.

## Results

Table 2 summarises the results for the specific and general cases posed in the first interview. The analogous information for the second interview is given in Table 3. The structures identified by the students as they worked are listed in tables 2 and 3 in the order in which they were observed and expressed using algebraic symbolism, although the students did not use that system.

Student	Specific cases	General case
S1	$y = x + 3$	$y = x + 3$
S2	$y = x + 3$ $y = x + x$	$y = x + 3$
S3	$y = x + 3$	$y = x + 3$
S4	$y = x + x$ $y = x + 3$ $y = x + x$	$y > x$

**Table 2: Structures identified in the first interview**

Further to the data in Table 2, each student identified one or two structures for the specific cases during the interview. Overall, three types of structures were observed in the particular and general cases, namely:  $x+x$ ,  $x+3$  and  $y>x$ . In the following extract of the interview, S4 identified different structures for the specific cases, as listed in the table in chronological order.

- I (Interviewer): What happened when you put 8 balls in the machine?
- S4 (Student 4): If there were 8, we add another 8, 16 balls.
- I: I'm going to write down the numbers you give me. When we put 5 balls in, how many came out?
- S4: 8
- I: And if we put 2 in, how many came out?
- S4: 4, I add 2+2

All four students generalised the functional relationship verbally (Table 2, last column). Three identified the structure as  $y = x+3$ , which they expressed verbally in different ways. S1 and S3 generalised both the specific cases (spontaneous generalisation) and the general case (prompted generalisation). S2 and S4 generalised only when they were prompted. S1 first gave examples of specific cases and then generalised by adding that the answer was found by adding 3: '1 ball we get 3, 2 balls we get 5, 3 balls we get 6, 4 balls we get 7. You always have to add 3. One million, you get

1 million and three.’ That answer was classified as prompted generalisation because the student formulated it when asked the general case question (Figure 2). S4, in turn, noted that ‘more balls come out than went in’, generalising without quantifying: ‘I know the machine spits out identical balls and what I know is that inside it has lots more balls’ (prompted generalisation). The other two students’ answers showed that they were thinking in terms of  $x+3$ . Three students identified the structure correctly ( $x+3$ ) in both the general and the specific cases. Table 3 lists the structures identified in the second interview.

Student	Specific cases	General case
S1	$y = x + 4$	$y = 4x$ $y = x + 4$
S2	$y = x + x$ $y = x + 4$	$y = x + 4$
S3	$y = x + 4$	$y = x + 4$
S4	$y = x + 4$ $y = x + x$	$y > x$

**Table 3: Structures identified in the second interview**

As in the first interview, students identified one or two structures for the specific cases. Three types of structures, including the ones given for the general case, were found:  $x+4$ ,  $4x$  and  $x+x$ . S2 and S4 exhibited the same type of structures as in the first interview, identifying the relationship in the specific cases to consist in doubling the value given. Generalisation was expressed verbally by all four students. The structures observed in their generalisations were:  $4x$  and  $x+4$ . The second was identified by all the interviewees. S1’s initial assertion that the age of the older superhero was found by ‘multiplying by four’ was indicative of their difficulty in distinguishing between addition and multiplication. Student S4 generalised the relationship to be  $x+4$  saying: ‘you have to add plus 4’. S2 and S3 both instantly answered that what they had to do was ‘add plus 4’. S1 generalised both the specific cases (spontaneous generalisation) and the general case (prompted generalisation). S2, S3 and S4 generalised only when prompted. The following extract exemplifies S1’s spontaneous generalisation when answering questions about specific situations.

I (Interviewer): when Iron Man was 5 years old Captain America was 9, when Iron Man was 7 Captain America was 11 and when Iron Man was 3 Captain America was 7. Can you tell me how those numbers are related?

S1 (Student 1): Captain America always wins: he’s 4 years older.

## Comparison of interviews

In the first and second interviews, S1 and S3 identified only one structure, correctly in both cases. S2 and S4 both identified more than one structure, likewise in both interviews. In the second interview S2 continued to identify  $x+x$ , although in the specific cases only, ultimately identifying the right structure as the interview proceeded. The contrary was observed in S4, who incorrectly identified the structure  $x+x$  in the second interview. Fewer differences were observed around the general case. S2

and S3 correctly identified the structure, whereas S1 initially identified a multiplicative structure in the second interview,  $4x$ , despite having correctly identified the structure in the first. In the second interview S4 correctly identified the relationship between the variables, having failed to do so in the first. All the students correctly identified at least one structure in the specific or general cases and all expressed generalisation in at least one case. In the second interview, however, only one student, S3, identified the sole same structure in the specific and general cases. Two students did so in the first interview. While seeing no clear structure in the specific cases, S4 correctly identified it in the general case. Generalisation was expressed in various ways in both interviews. In the second interview, only S1 generalised spontaneously, whilst in the first both S1 and S3 did so.

## Discussion and conclusions

This paper presents evidence of functional thinking in second-year primary school students. Like the fifth-year primary students who participated in the Pinto and Cañadas (2017a) study, most of the second-year pupils in our survey generalised structures, identifying the same structure in the specific and the general cases in the first and second interviews. Their answers were found to be coherent. The number and variety of the structures identified were greater in the first interview. Although the students might have identified  $2x$  instead of  $x+x$  for the specific cases in both interviews, none did. Students evidenced the  $x + x$  structure more easily than the  $2x$  because of the kind of structure (additive versus multiplicative structure). All the students expressed generalisation verbally, a finding consistent with the Cañadas and Fuentes (2015) results. All the students generalised in both the first and the second interview. That finding differed from the results reported by Pinto and Cañadas (2017b) for third-year students, only one of whom generalised. In the second interview generalisation was consistently and simply phrased as ‘adding plus 4’. In our study generalisation was normally prompted. In one case, S4 in the first interview, expressed the general relationship as  $y > x$ . This student was able to see that ‘y is always greater’, without quantifying to what extent is greater.

Whilst differences between the intermediate and advanced groups was not explored in this study, the findings showed that students’ classification in one or the other had no impact on their ability to correctly identify structures. In other words, the advanced students did not correctly identify more structures than the others. In fact, the contrary was found: S1, an intermediate group student, was the only one to correctly identify the structure involved in the specific and general cases in both interviews. Work to enlarge on this study is ongoing to determine how the working sessions might have affected the differences between the two interviews.

# Comparing the structure of algorithms: The case of long division and log division

Christof Weber

School of Education, University of Applied Sciences Northwestern Switzerland,  
Muttenz, Switzerland; christof.weber@fhnw.ch

*This paper is a theoretical contribution to the comprehension of logarithms by means of comparing algorithms. First an algorithmic approach to the logarithm (so-called log division) is introduced, which then is compared with the standard division algorithm (long division). By working out mathematical correspondences and differences between the two algorithms, this approach focuses on structural aspects of two mathematical operations and their relations. Comparing algorithms in classrooms is proposed as a way of algorithmic thinking that would go beyond rote memorization.*

*Keywords: Mathematical algorithms, logarithms, long division, comparison, algorithmic thinking.*

## Introduction

Algorithms have played a central role in mathematics since antiquity. Examples such as Heron's method (for computing square roots) and the Euclidean algorithm (for computing the greatest common divisor) are impressive evidence of this. Their development is still an integral part of mathematical research (Chabert, 1999; Ziegenbalg, 2016). Accordingly, mathematics education until the late Middle Ages was primarily computational education, that is, the teaching and practice of computational methods (Graumann, 2002; Ziegenbalg, 2016). Still today in school instruction of algorithms occupy an important place. In every case algorithms are “a finite sequence of explicitly defined, step-by-step computational procedures which ends in a clearly defined outcome” (Wu, 2011, p. 57). It is hardly surprising, then, that algorithms and also dealing with algorithms is sometimes regarded as one of the “central ideas” for mathematics education (Heymann, 2003).

As can be seen from the above examples, each algorithm always solves a whole class of structurally related computational problems. Another strength is that we do not have to worry about how it works or validate the result since it turns a problem into a routine task. This is a substantial relief for the user and effectively clears the way to tackle new, unresolved issues. The flip side of this liberating mindlessness is that users can also mechanically execute an algorithm without being able to justify it, to know the limits of its applicability, etc. Thus, learning algorithms takes place within a field of tension between mechanical memorizing and meaningfully acquiring, in short: *memorization by rote vs. conceptual understanding* (Baroody, 2003; Wu, 1999).

The dangers of rote learning have been empirically established in several studies in the case of standard algorithms for the four arithmetic operations (e.g. Kamii & Dominick, 1998). This could also be the reason why some authors contrast knowledge of standard algorithms with conceptual understanding (Baroody, 2003; Fan & Bokhove, 2014), or why the term “algorithmic thinking” is sometimes understood rather in a negative sense. Occasionally, a reduction or even a banishment of certain standard algorithms from the curriculum is advocated (for instance in Canada, see Fan & Bokhove, 2014, p. 482, or in North Rhine-Westphalia / Germany, see Krauthausen, 2018, p. 91).

## Understanding algorithms in the classroom and in teacher education

However, not all authors go so far, but rather focus on the role of the teacher: “[Rote learning might take place] when the teacher does not possess a deep enough understanding of the underlying mathematics to explain it well. The problem of rote learning then lies with inadequate professional development and not with the algorithm” (Wu, 1999, p. 6). To defuse this problem, there are different suggestions for classroom instruction and teacher education. They can be divided into two strands:

1. A first strand of proposals recommends that students not be provided with ready-made algorithms and detailed directions for their use. Instead, they should be encouraged to *invent their own methods and individual strategies* for solving computational problems. In mathematics education at primary school level, this includes informal mental arithmetic as well as informal pencil-and-paper arithmetic. The point is, then, that students develop individual strategies in which they operate not with the individual digits of numbers but always with “numbers as wholes”, that are decomposed in meaningful ways. In the case of the division, this could mean subtracting easy multiples of the divisor from the dividend until the dividend has been reduced to zero or the remainder is less than the divisor, then adding together the partial quotients to obtain the quotient (“partial quotient division”, Kilpatrick, Swafford, & Findell, 2001, p. 221).
2. Another strand of suggestions recommends *comparing standard algorithms or individual strategies* in the classroom as a way to understand why they work. For example, Bass (2003) suggests that students in the classroom compare standard with alternative algorithms in terms of their generality or efficiency, while Simonsen and Teppo (1999) suggest this kind of comparison in teacher training programs. Empirical studies of Durkin, Star and Rittle-Johnson (2017) show in which way learners can benefit from comparing different worked-out strategies for solving the same linear equation. There is also a certain tradition in teacher education that elementary teacher trainees must compare standard algorithms such as long division in base-10 with the same algorithm in other number bases in order to understand better the connection between number bases and algorithms (Padberg & Büchter, 2015). The aim is to see the algorithm not only as a recipe and to perform it fluently, but also to see it in its relation to other algorithms by focusing on certain structural aspects.

The present article focuses on the second approach, the comparison of algorithms, in the context of the teaching and learning of logarithms. This calls forth in particular the following questions:

- *How can the logarithm be described algorithmically?*
- *What is the mathematical relation between the algorithmic description of logarithms and that of division? In what respect do the two algorithms correspond, and in what respect do they differ?*

## Comparing log division with long division

Primary students learn that division of integers can be seen as partitive (fair-sharing) division as well as quotative (measurement) division (Greer, 1992). It is the measurement interpretation that allows the division to be conceived as an algorithm: in the long division algorithm, the divisor is repeatedly subtracted from the dividend until the remainder is as close to zero as possible (for a justification see Wu, 2011, pp. 110–122). Mathematically, this has to do with the fact that the divi-

sion is the inverse operation of multiplication and multiplication can be conceived as repeated addition (at least for whole numbers). Now, as logarithms are an inverse of powers, and powers are repeated multiplication, the logarithm can be treated algorithmically in a similar way—as a *repeated division* (Vos & Espedal, 2016; Weber, 2016). This allows logarithmic values to be calculated algorithmically. In keeping with the name of the standard division algorithm, “long division”, I call the corresponding algorithm “log division”. It is described now in order to then compare it with long division.

### Log division: description of the algorithm

Repeated subtraction and repeated division can be naturally applied to calculate quotients and logarithms that come out even and yield integer answers:  $8 : 2$  equals 4 since  $\underbrace{8 - 2 - 2 - 2 - 2}_{4 \times} = 0$ , and

in the same way,  $\log_2 8$  equals 3 since  $\underbrace{8 : 2 : 2 : 2}_{3 \times} = 1$ . Relying on repeated division, I now give a

step-by-step description of how the log division algorithm works (Goldberg, 2006; Weber, 2016). Suppose you have to compute  $\log_{16} 32$  (see Figure 1):

*Step 1:* Calculate how many times the argument (32) can be divided by the base (16) before the result is less than the base. In our case, 32 can be divided by 16 only one time (because dividing 32 by 16 two times, the quotient would be less than 1). You record this result of 1 above the bracket (noted as . in Figure 1).

*Step 2:* Next, you calculate the base raised to this result:  $16^1 = 16$ . You place this number beneath the argument of the logarithm and divide (instead of subtracting as in long division) the argument by this value ( $32 : 16^1$ ). Note the result (2) as a remainder underneath.

*Step 3:* You raise the remainder to the 10-th power (recall that in the same step in long division you bring down a further digit from the dividend, in effect multiplying the original remainder by 10). Note the result as the new argument:  $2^{10} = 1024$ .

*Step 4:* If (as in our example) the new argument does not equal 1, go back to the Step 1, if it equals 1 (not 0 as in long division), the process has come to an end.

*Conclusion:* By cycling through the steps 1 to 4 until arriving at the argument 1, you obtain the single digits of the decimal expansion of the result. In our example, you reach the remainder of 1 after two additional cycles (producing 1, 2, 5 as the successive exponents of 16.) Stringing the numbers together, the decimal expansion of  $\log_{16} 32$  is found to be to be 1.25.

Figure 1 shows not only the computation of  $\log_{16} 32$  digit by digit, but also the corresponding logarithmic expressions that reveal what the algorithm actually “does.” It also shows that the algorithm works not only for natural, but also for non-integer results. In order to emphasize the *mathematical analogy to division*, those who use the colon “:” notation for long division (for instance in countries where Romance languages or German are spoken) could use the non-standard tricolon “:” notation for log division, for instance  $\log_{16} 32 = 32 : 16$  (for the historical background, see Weber, 2016).

Those who use the bracket notation “ $\sqrt{\phantom{x}}$ ” (for instance in English-speaking countries, Mexico or Japan) could use the notation “ $\sqrt{\phantom{x}}\sqrt{\phantom{x}}$ ” for log division,  $\log_{16} 32 = 16 \sqrt{\phantom{x}}\sqrt{\phantom{x}} 32$  (Weber, 2019).

$\log_{16} 32 = 32 : 16 = 1.25$ $\begin{array}{r} : 16 \left( = 16^{\boxed{1}} \right) \\ \hline 2 \\ 2^{10} = 1024 \\ : 256 \left( = 16^{\boxed{2}} \right) \\ \hline 4 \\ 4^{10} = 1048576 \\ : 1048576 \left( = 16^{\boxed{5}} \right) \\ \hline 1 \end{array}$	$\log_{16} 32 =$ $= \log_{16} (16^{\boxed{1}} \cdot 2) = \boxed{1} + \log_{16} (2)$ $= 1 + \frac{1}{10} \cdot \log_{16} (2^{10})$ $= 1 + \frac{1}{10} \cdot \log_{16} (1024)$ $= 1 + \frac{1}{10} \cdot \log_{16} (16^{\boxed{2}} \cdot 4) = 1. \boxed{2} + \frac{1}{10} \cdot \log_{16} (4)$ $= 1.2 + \frac{1}{100} \cdot \log_{16} (4^{10})$ $= 1.2 + \frac{1}{100} \cdot \log_{16} (1048576)$ $= 1.2 + \frac{1}{100} \cdot \log_{16} (16^{\boxed{5}} \cdot 1) = 1.2 \boxed{5}$
--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

**Figure 1: Log division algorithm (applied to  $\log_{16} 32$ ) – to the left. Stepwise explanation – to the right**

### Comparing the mathematical structure

In order to not only explain the algorithms by means of examples, an approach to a more thorough, mathematical justification is given now, in two steps: To start with, I explain why division is equivalent to repeated subtraction and why finding the logarithm is equivalent to repeated division, which allows us then to compare the respective algorithms with each other.

For this we first consider the following mathematical *equivalence relations*:

- For the division of a whole number  $b$  by a whole number  $a$  ( $a \neq 0$ ) one has:

$$? = b : a \iff ? \cdot a = b \iff b - ? \cdot a = 0$$

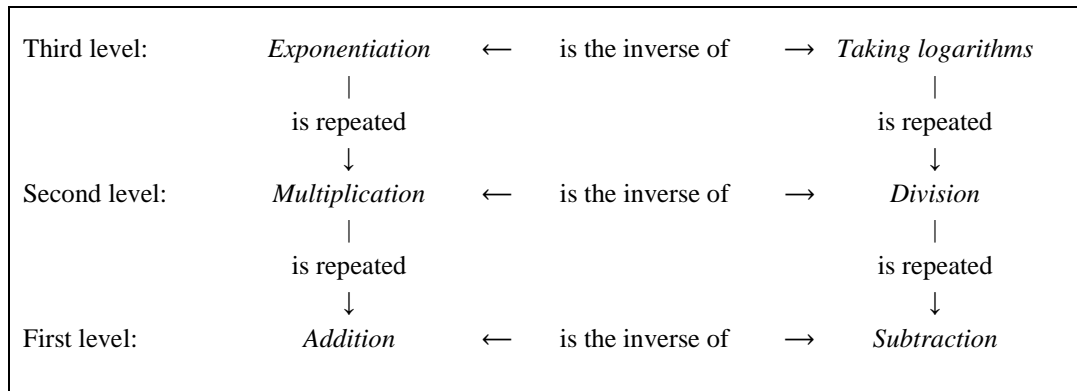

- For the logarithm of a natural number  $b$  to a natural-number base  $a$  ( $a \neq 1$ ) one has:

$$? = \log_a b \iff a^? = b \iff b : a^? = 1$$

From these relations follow several conclusions:

- The quotient  $b : a$  gives (in the context of whole numbers) “how many  $a$ ’s are in  $b$ ” as a *summand* (Wu, 2011, p. 103). On the other hand, the logarithm  $\log_a b$  (or  $b : a$ , respectively) gives how many  $a$ ’s are in  $b$  as a *factor*.
- The two equivalence relations structurally resemble each other, since they are each based on a respective inverse operation. In this respect, they are *analogous* to each other. However, they operate at different hierarchy levels: while division and multiplication are second-level operations,

built upon the first-level operation of subtraction, logarithms and powers are third-level operations, built upon the second-level operation of division (see Figure 2).

**Figure 2: Hierarchy levels of arithmetic operations**

3. According to conclusion 1 above, *algorithms* can be derived to calculate the value of the corresponding quotient or the corresponding logarithm. Thus, the algorithm for long division counts how many times the number  $a$  is subtracted from the number  $b$ . The log division, on the other hand, counts how many times the number  $a$  divides the number  $b$ . Because of conclusion 2, the two algorithms are also analogous to one another; in particular the individual calculation steps correspond:

- Analogous to the fact that in the long division the remainders are multiplied by 10 (a second level operation), the remainders in the log division must be raised to the power 10 (see the corresponding third level operation) (see Step 3, above).
- The algorithm of long division ends as soon as the repeated subtraction leads to the remainder 0 (the additive identity). Accordingly, log division terminates as soon as the repeated division leads to the “remainder” 1 (the multiplicative identity) (see Step 4). If this occurs, the result is an integer or a finite decimal expansion (see Figure 1), otherwise not.

In addition to this analogy and its consequences, there are also two significant *differences* between the two algorithms that should be kept in mind:

1. Numbers are usually encoded as decimal numbers, meaning they are decomposed as a series of digits, each weighted by a power of ten, and added together. As with all standard algorithms of arithmetic, the strength of the long division is that it does not divide the dividend as a whole, but essentially digit by digit (Wu, 2011, p. 56). That this can be done is due to the fact that division distributes over addition,  $(b_1 + b_2) : a = b_1 : a + b_2 : a$ . In order to make the division algorithm more accessible in the classroom, it is sometimes suggested to discuss the already-mentioned partial quotient method, which treats the dividend as a whole entity, from which easy multiples of the divisor are subtracted (see above).

Unfortunately, logarithms do not distributive over addition,  $\log_a(b_1 + b_2) \neq \log_a b_1 + \log_a b_2$ . Hence it is not possible to march along, calculating one digit of the logarithm for each digit of the argument as with division: While  $32 = 30 + 2$ ,  $\log 32 \neq \log 30 + \log 2$ . As a result, you have to pay attention from the beginning to all the digits of the number, similar to the partial quotients division (see Step 1).

2. The multiplication operation, for example  $2 \cdot 4 = 8$ , can be inverted in two ways: Either you are interested in the first factor  $? \cdot 4 = 8$ , or the second factor ( $2 \cdot ? = 8$ ). While the first factor can be found via repeated subtraction (measurement interpretation),  $8 - 4 - \dots - 4 = 0$ , the second ques-

tion corresponds to the fair-sharing (partitioning interpretation),  $8 \overset{? \times}{\underbrace{- ? - ? - ? - ?}_{4 \times}} = 0$ , an equation

that can only be immediately solved by guessing. Since however multiplication is commutative, the question of the second factor can always be handled as a question regarding the first factor:  $2 \cdot ? = ? \cdot 2$ . To sum up: *Since multiplication is a binary operation, finding its inverse can be understood in two ways, but due to its commutativity, both lead in the end to one and the same operation, division.* (Wu, 2011, pp. 99–100)

In the same way the operation of exponentiation, for example,  $2^3 = 8$ , can be inverted in different ways, depending on whether you are interested in finding the exponent  $2^? = 8$ , or the base  $?^3 = 8$ . The answer to the first question can be calculated through repeated division step-by-step:  $8 \overset{? \times}{\underbrace{: 2 : \dots : 2}_{3 \times}} = 1$ , while the second question leads to the equation  $8 \overset{? \times}{\underbrace{: ? : \dots : ?}_{3 \times}} = 1$ . In contrast

to multiplication, the one form of inverse cannot be applied to find the other one, since exponentiation is not commutative. In other words: *On account of its non-commutativity ( $a^b \neq b^a$ ), exponentiation has two distinct inverse operations: taking the logarithm,  $\log_2 8 = 3$ , as well as extracting the root,  $\sqrt[3]{8} = 2$ .* Accordingly, the method of repeated division can only be applied to solve inverse questions regarding the *exponent* of a power, but not those concerning its *base*.

## Conclusion and questions

There is a certain tradition in mathematics education to place concepts of elementary mathematics into meaningful contexts in order to make them easier to learn, and to promote efficient and flexible application later on (e.g., for long division, see Pratt, Lupton & Richardson, 2015). For secondary schools, the situation is a bit different. So while it may be possible to occasionally identify meaningful contexts, with increasingly abstract content this is not necessarily desired. For concepts such as the logarithm, which can be conceptualized algorithmically, it therefore makes sense to compare them with other mathematical algorithms in order to make them accessible and to understand why they work (Bass, 2003). While I have described the algorithmic approach of “log division” previously, the correspondences and differences between the algorithms seem to have never been worked out before.

This paper also raises various questions. First of all, the question of the mathematical generalization of the log division from natural to rational bases and arguments remains open. The question of the

explanatory power of the log division is also not covered here, that is, in which situations our algorithmic conceptualization of logarithms can serve as a basis for solving tasks and for reasoning (for instance, one could argue that logarithms are not defined for negative arguments because a negative number divided repeatedly by the positive basis will never yield 1, see Weber, 2016). Another group of questions is empirical in nature and asks about the effects and pitfalls that an algorithmic approach combined with comparison would have in teacher education and in subsequent classroom instruction (for a classroom teaching experiment to introduce logarithms by log division, see Weber 2019). In particular, in which ways might comparing the structure of algorithms foster conceptual understanding?

### Algorithmic and algebraic thinking

Last but not least, the results of this contribution might be used to clarify the construct “algorithmic thinking” in mathematics education: comparing algorithms might be a way of dealing with algorithms in the classroom beyond just learning to perform them. For instance, in order to bring out further aspects of the construct, the cognitive processes of students and teachers could be studied when they work on the new algorithm of log division by relating it to the familiar long division.

Teaching algorithms by comparing them, as outlined above, focuses on seeing structure and relationships between mathematical operations. While seeing structure in numerical expressions can be seen as algebraic thinking at primary level (Kaput, 2008), comparing algorithms might be seen as a specific form of algebraic reasoning at the secondary level (Kieran, 2018). Kaput’s view that “the heart of algebraic reasoning is comprised of complex symbolization processes that serve purposeful generalization and reasoning with generalizations” (2008, p. 8), raises more questions related to the contents of this paper. For instance, at primary and secondary school, algorithms are never explained or justified in full generality, but by generic examples. To what extent is this characteristic similar to teaching early algebraic reasoning by generic arguments? Furthermore, any given algorithm does not solve just a single task, but a class of multiple problems. To what extent is this characteristic similar to algebraic reasoning, understood as “reasoning with generalizations”? Future research will have to clarify and answer these and several other questions.

*In this study we use latent class and distractor analysis as well as qualitative analysis of cognitive interviews to investigate how student responses to concept inventory items may reflect different patterns of algebraic conceptual understanding and procedural fluency. Our analysis reveals three groups of students, which we label “similar to random guessing”, “some procedural fluency with key misconceptions”, and “procedural fluency with emergent conceptual understanding”. Student responses also revealed high rates of misconceptions that stem from misuse or misunderstanding of procedures, and whose prevalence correlates with higher levels of procedural fluency.*

*Keywords: Elementary algebra in college, conceptual understanding, concept inventory.*

In the US, elementary algebra and other developmental courses have consistently been identified as barriers to student degree progress and completion in college, with only as few as one fifth of students ever successfully completing a credit-bearing math course (e.g., Bailey, Jeong, & Cho, 2010). There is evidence that students struggle in these courses because they do not understand fundamental algebraic concepts (e.g., Givvin, Stigler, & Thompson, 2011; Stigler, Givvin, & Thompson, 2010), and many research studies have documented the negative consequences of learning algebraic procedures without any connection to the underlying concepts (e.g., Hiebert & Grouws, 2007). However, developmental mathematics classes currently focus heavily on recall and procedural skills without integrating reasoning and sense-making (Goldrick-Rab, 2007; Hammerman & Goldberg, 2003). This focus on procedural skills in isolation may actually be counter-productive, in that students may often attempt to use procedures inappropriately because they lack understanding of when and why the procedures work (e.g., Givvin et al., 2011; Stigler et al., 2010).

In this paper we explore student responses to conceptual questions at the end of an elementary algebra course in college. We combine quantitative analysis of responses (using latent class analysis and distractor analysis) with qualitative analysis of cognitive interviews to better understand different typologies of student reasoning around some basic concepts in algebra, and to better understand how conceptual understanding and procedural fluency may relate to one another in this context.

### **Research questions**

Is there a latent class structure that adequately represents the heterogeneity of item responses on

an algebra concept inventory among college developmental algebra students? If so, are patterns observed with distractor analysis, procedural assessment scores, and qualitative analysis of cognitive interviews consistent with the class structure, and can they contribute to class interpretation?

## Theoretical framework

In this paper we use Fishbein's (1994) typology of mathematics as a human activity as a framework for analyzing student responses and thinking about how conceptual understanding and procedural fluency might inform one another. Fishbein outlines three basic components of mathematics as a human activity: 1) *the formal component* (which we call *conceptual understanding*), which consists of axioms, definitions, theorems and proofs, which need to be "invented or learned, organized, checked and used actively" (p. 232) by students; 2) *the algorithmic component* (which we call *procedural fluency*), which consists of skills used to solve mathematical problems in specific contexts and stems from algorithmic practice; and 3) *the intuition component*, which is an "apparently" self-evident mathematical statement that is accepted directly with the feeling that no justification is necessary.

In this study we use the term conceptual understanding not only to denote a formal understanding of abstract concepts (e.g. axioms), but also of how, when, and why procedures can be used. This is in contrast to procedural fluency in standard problem contexts, in which a student may be able to quickly solve particular types of standard problems correctly but may not understand of how, why, or when these methods work. We say that an item tests conceptual understanding if a student must use *logical reasoning* grounded in mathematical definitions to answer correctly, and it is *not* possible to arrive at a correct response *solely* by carrying out a procedure or restating memorized facts. We define a *procedure* as a sequence of algebraic actions and/or criteria for implementing those actions that could be memorized and applied correctly with or without a deeper understanding of the mathematical justification. Using these definitions, no question is wholly conceptual or procedural, but falls on a spectrum. We recognize that the definition of conceptual understanding and its relationship to procedural fluency has been much debated in the research community with no clear consensus (e.g., Baroody, Feil, & Johnson, 2007; Star, 2005), and that the two forms of knowledge are interrelated (e.g., Hiebert & Lefevre, 1986; National Research Council, 2001).

In fact, each of Fishbein's three components may interact. Intuition may facilitate learning when it is consistent with logically justifiable truths (i.e. the formal component) but may also be an obstacle to learning in cases where it is inconsistent. In this paper we explore how students who develop algorithmic/procedural skills in isolation from formal/conceptual understanding may be prone to developing intuitions that are inconsistent with logically justifiable truths, and as a result, may exhibit simultaneously increased procedural fluency in standard problem contexts and decreased conceptual understanding. We consider how student justifications of answer choices may exhibit intuition components (which may be either correct or incorrect), and we consider how these intuitions may relate to both the processes of developing procedural fluency as well as conceptual understanding.

## Methods

This study focuses on student responses to the multiple choice questions on the Elementary Algebra Concept Inventory (EACI). For details on the development and validation of the EACI, see Wladis et al. 2018). Here we focus on 698 students who took the inventory at the end of their elementary algebra class in 2016-2017. In order to supplement quantitative data, 10 cognitive interviews were conducted towards the end of the semester with students who were enrolled in an elementary algebra class and were analyzed using grounded theory (Glaser & Strauss, 1967), although a full qualitative analysis is not presented here due to space constraints. All students currently enrolled in the course were recruited via email to complete the EACI and then to be interviewed about their thinking immediately afterwards. The distribution of interviewees among the three classes was not significantly different from the whole quantitative sample.

In this paper we used latent class analysis (LCA) of the nine binary scored (right/wrong) multiple-choice items on the inventory. LCA is a latent variable model that presumes that items are locally independent conditional on a discrete nominal latent variable (e.g., Collins & Lanza, 2010).

## Description of the classes

Latent class analysis on binary (correct/incorrect) scoring of the items was used to look for common response patterns among the students in the quantitative sample, and this analysis revealed three distinct classes of students. While latent class analysis was used to generate the three classes, more fine-grained analyses were needed to generate potential interpretations of each class. After the initial classes were generated by latent class analysis, item response patterns, distractor analysis, and qualitative coding of cognitive interviews were used to generate characterizations of each class, and evidence was found among these different complementary approaches for the following potential characterizations of each class. The remainder of this paper describes in more detail the different approaches that were used to develop the class interpretations presented here:

- C1 (27%): Answers to most items are indistinguishable from random guessing, likely due to low procedural/conceptual knowledge, low self-efficacy, and/or low motivation.
- C2 (28%): Likely have some procedural skills but limited conceptual understanding.
- C3 (45%): Likely have procedural skills and emergent conceptual understanding.

These descriptions emerged from different analyses of the data. Firstly, we consider the response patterns of students from each of the three classes, and we see some clear trends (see Figure 1).

Figure 1: LCA profiles of student responses in each class

Student responses in class 1 do not vary much from what would be expected for random guessing on four-option multiple choice items. While all of the items on the test were designed to test

conceptual understanding, some of them (items 2, 3, 5, and 6) use more abstract or non-standard formulations of algebraic ideas. Class 2 answers significantly worse than chance on questions 2 and 6 because of the presence of attractive distractors that likely tap into misconceptions related to the misuse of procedures. Classes 2 and 3 are distinguished by improved performance on the items overall as well as different proportions of key misconceptions. Students who passed the class were most likely to be in class 3, then class 2, and least likely to be in class 1. An end of course standardized assessment that measures procedural fluency in standard problem contexts showed a similar outcome. To illustrate how different response patterns distinguish these three classes, we performed a distractor analysis and analyzed cognitive interviews for three exemplars: items 2, 4, and 6. We used the Bayes modal assignment to determine the class membership of interviewees.

### Three example questions: illustrating different class response patterns

First we consider Item 4:

4. Which of the following is a result of correctly substituting  $x - 4$  for  $y$  in the equation  $3y - 2 = y^2 + 1$
- $3x - 4 - 2 = x - 4^2 + 1$
  - $3x - 4 - 2 = x^2 - 4^2 + 1$
  - $3(x - 4) - 2 = (x - 4)^2 + 1$
  - $3x - 3 \cdot 4 - 2 = x^2(-4)^2 + 1$

The correct answer is c. C1's responses are scattered in a pattern consistent with random guessing (see Figure 2). By contrast, C2 and C3 have a high probability of choosing the correct response, with C3's probability significantly higher than C2. This item is behaving the way we would expect if C1, C2, and C3 were ordered on conceptual ability. Selecting c is also highly correlated with scores on the procedural exam, corresponding to a score that is higher by 10.8 percentage points. ( $p=0.000$ )

Figure 2: Item 4 Distractor Analysis

Looking at student interview responses reinforces our interpretation of the three classes, and reveals how higher classes appear to have more robust and correct intuitions about substitution.

**C1 (chose B):** It says  $x - 4$  for  $y$ , this is what I think like because  $y^2$ . It could be like changed to a  $4^2$ . I put together like  $3x - 4 - 2 = x^2 - 4^2 + 1$ . [I didn't pick c or d because] they [pointing to the  $x - 4$  in the item stem] didn't have no bracket around them. [I picked B with the  $x^2$  in it instead of A, which doesn't have the  $x^2$ ] because  $x$  equals  $y^2$  so it has to have an  $x^2$  in it because the  $y$  is squared there.

**C2 (chose C):** So usually when a math question says, "substituting" that's basically putting the numbers that they give you into  $x$  or  $y$  that they say to put it. I automatically substituted it in, and my correct answer was  $3(x - 4) - 2$ ... I didn't pick any

other answer, because I didn't see the parentheses.

**C3 (chose C):** I didn't choose A because when trying to multiply the  $y$ , which is  $x - 4$ , you have to put the parenthesis behind 3, unless you already multiplied 3 times  $x - 4$ ... [choice D] does have parenthesis on  $-4$ , but then, it will be missing the complete equation for  $y$  because  $-4$  is not the only equation that equals to  $yy$  is  $x - 4$ .

In these examples, the C1 student demonstrates an intuition about substitution that the  $y$  should be replaced with  $x - 4$  in the equation, but this does not include an awareness of the equation structure (e.g., that the  $x - 4$  must be treated as a single unit). The C2 student also demonstrates a partially- correct intuition that parentheses must be used around whatever is being substituted, but doesn't execute this procedure completely correctly on both sides, and doesn't demonstrate any awareness of *why* the parentheses are necessary. In contrast, the C3 student shows both an awareness of the need for the parentheses and an understanding of *why* the parentheses are logically necessary— because without them, the structure of the equation will be altered. Now we consider item 6, which shows a different pattern of responses:

6. A student is trying to simplify two different expressions:

- i.  $(x^2y^3)^2$     ii.  $(x^2 + y^3)^2$

Which one of the following steps could the student perform to correctly simplify each expression?

- For both expressions, the student can distribute the exponent.
- The student can distribute the exponent in the first expression, but not in the second expression.
- The student can distribute the exponent in the second expression, but not in the first expression.
- The student cannot distribute the exponent in either expression.

Figure 3: Item 6 distractor analysis

The correct answer is b. C2 and C3 were strongly attracted to option a (see Figure 3), likely because they have intuitions stemming from their experiences with procedures associated with the distributive properties, but they do not recognize the critical differences between distributing multiplication versus exponents—likely because they have no deeper conceptual understanding of how the distributive property works. Unlike item 4, selecting the correct answer is negatively correlated (and selecting the attractive distractor was positively correlated) with scores on the procedural exam—students who selected the incorrect option a scored on average 7.1 percentage points higher on the procedural exam ( $p < 0.000$ ) than others. This suggests that in this context (where procedures are typically taught in isolation from concepts) procedural fluency in standard problem contexts can be inversely related to conceptual understanding of the distributive properties.

Looking at student interview responses reinforces our interpretation of the three classes, and sheds light on how intuitions developed from procedural practice may impede conceptual understanding.

**C1 (chose B):** [The difference between the first and second equation] is that there's a plus right there [pointing to the second equation]. I think for this one [pointing to the second equation], you have to add and for this one [pointing to the first equation] you don't.... Actually, I think like over here [pointing to the second equation] you add a 3. 3 plus 2. [For the first one] you do  $x^2$  times  $x^2$  and  $y^3$  times  $y^3$ .

**C2 (chose A):** I feel like that's correct because in order to solve  $x^2$  and  $y$ , you have to distribute.... Because I've seen problems like this before and it's like you have to solve it, there is no not solving it because there is no ... there is no solution.

$$\begin{array}{ll} \text{i. } (x^2y^3)^2 & = x^4y^6 \\ \text{ii. } (x^2+y^3)^2 & = x^4+y^6 \end{array}$$

**C3 (chose A):** That's how you kind of get rid of the parenthesis and get rid of the outer exponents by distributing it in the inside. Whether it's with another exponent or with a number... You want to add or multiply that exponent [outside the parentheses] to the ones inside the parentheses but I can't remember whether you add or multiply...

In these examples, the C1 student notices that there is a difference between the two equations and has an intuition that it is important, but doesn't actually know how to perform the distribution correctly. For the C2 and C3 students, we see a number of ways in which students are citing incorrect intuitions that stem from algorithmic experience—we have included only a few samples here. None of the students interviewed was able to describe when and why it is possible to distribute—they all cited incorrect intuitions related to procedural methods that they had learned in class. Next we consider item 2, which reveals another interesting pattern of responses:

2. Consider the equation  $x + y = 10$ . Which of the following statements must be true?
- There is only one possible solution to this equation, a single point on the line  $x + y = 10$ .
  - There are an infinite number of possible solutions, all points on the line  $x + y = 10$ .
  - This equation has no solution.
  - There are exactly two possible solutions to this equation: one for  $x$  and one for  $y$ .

For this question, the correct answer is b, (the most popular choice for students in classes 1 and 3) but no examinee in class 2 chose it (see Figure 4).

Figure 4: Item 2 distractor analysis

They were strongly attracted to option d, which was also the second most popular choice for students in both of the other classes, although at a much lower rate. Option d is a common response from students asked to solve a system of linear equations for  $x$  and  $y$ , which may explain its popularity. Both C2 and C3 were attracted to option d, again suggesting they are attempting to apply inappropriate procedural reasoning. This item is responsible for the notable separation

between C2 and C3 because no examinee in C2 chose the option b, the correct response. Looking at student interview responses reinforces our interpretation of the three classes, and sheds light on students' reasons for choosing both correct and incorrect options.

**C1 (originally chose C, but drifted towards B in the interview):**  $x + y$  equals nothing so it can't be 10. Right?... [Maybe infinite means] what could be like possible? I don't know. Like equal number maybe?  $x + y = 10$ . It could be possible like it equals 10. [D isn't correct] maybe because  $x$  and  $y$  could be equal to anything?

**C2 (chose D):** What I assumed was the  $x$  term and the  $y$  term, you would have to substitute. And I know there are certain numbers that will add up to ten, so there could be two solutions, since there's only a  $x$  term and a  $y$  term... Like  $x$  could equal 5,  $y$  could equal 5... since it is two terms, so you could say two different solutions.

**C3 (chose B):** Ten could equal to many things. Like five plus five could equal ten. Nine plus one could equal ten. Seven plus three. That's why I chose that, because it could be any number that will equal to ten. It's not just one certain number.

The C1 student initially chose “no solution” because they didn't know what  $x$  and  $y$  could be, but as they discussed their answer, they started to relate this to the idea that  $x$  and  $y$  could be “anything”. While their reasoning is not strictly correct, they are beginning to explore the idea that  $x$  and  $y$  may have many possible values, and they show no evidence of faulty intuitions stemming from procedural practice. The C2 student exhibits an intuition about what the equation means (perhaps from standard substitution problems) to find a single solution, but they do not explore whether there might be others. They also confuse the number of solutions with the number of variables in the solution set, suggesting that their intuitions about the definition of a solution set are likely incorrect. The student from C3 describes how this equation could have multiple solutions, demonstrating some conceptual understanding of solution sets, including the fact that they describe the relationship between the two variables.

## Discussion and Limitations

This study revealed several trends. Firstly, roughly one quarter of students at the end of the course appeared to guess somewhat randomly on conceptual questions, likely because of low knowledge, self-efficacy, or motivation. However, cognitive interviews suggest that these students may be able to make some progress towards conceptual understanding by relying initially on more naïve reasoning and that they are not typically hindered by incorrect intuitions stemming from misuse of procedures. About one quarter of students demonstrated some mastery of procedures in standard problem contexts, but demonstrated many misconceptions related to misuse of procedures. In contrast, roughly half the class showed evidence of emergent conceptual understanding, with lower frequency of misconceptions related to misuse of procedures. For a number conceptual questions, particularly those that were more abstract or non-standard, conceptual understanding and procedural fluency were significantly strongly inversely related. Cognitive interviews revealed that this may happen when students develop incorrect intuitions stemming from the use of procedures.

Both local observation of courses at the research site, and national research literature on developmental mathematics classes in college (e.g., Goldrick-Rab, 2007; Hammerman &

Goldberg, 2003) provides evidence that almost all instruction in this context teaches procedures isolated from underlying concepts, so this research may be revealing patterns specific to this type of instruction—it may be that repeated procedural practice in isolation may worsen certain kinds of conceptual understanding. We note that this study did not attempt to link student response patterns to specific types of instruction—there is a pressing need for future research to examine this relationship in order to determine which types of instruction impact student growth in conceptual understanding.

# Forming basic conceptions in dealing with quadratic equations

Alexander Wolff<sup>1</sup>

<sup>1</sup>University of Hildesheim, Faculty of Mathematics and Applied Informatics, Hildesheim, Germany;  
wolff@imai.uni-hildesheim.de

*Keywords: quadratic equations, solving, transforming, understanding, basic conceptions.*

## Introduction

Transforming and solving quadratic equations, such as  $-2x^2 = -8$ , is part of the curriculum taught in school. To support the learning process of equations and their equivalent transformations, models such as the balance scale-, the box or the strip model, can be and are usually used in class (see Holzäpfel/ Barzel, 2010). The work and the support thereby reach its limits when dealing with negative coefficients in quadratic equations or by multiplying/dividing with negative numbers (see Vlassis, 2002). On the one hand its whole variety of formal expressions of quadratic equations and its equivalent transformations cannot be supported and visualized with the above mentioned models. On the other hand the work with the suggested models can lead to inadequate conceptions (misconceptions) of the mathematical concepts: E. g. facing problems to be able to interpret formal expressions such as  $2x^2 + 2 = x^2$  or  $2 = 3$  as equations as well (with an empty set of solutions). E.g. regarding the division of both sides of the equation by  $x$  or the extraction of the square root as an equivalent transformation. But working with models and forming content adequate conceptions for the learning process is indispensable. According to vom Hofe/ Blum (see 2016) the formation of basic conceptions (Grundvorstellungen) belongs to a competent and sensible dealing with mathematical concepts. But which basic conceptions, that students are about to form in the learning process, can be cited up? Two basic conceptions are cited normatively and visualized in a model further down. They allow to interpret a quadratic equation and its equivalent transformations illustratively in a graphical (or tabular) way and consequently grasp the core of understanding

## Model

### Basic conception 1:

A quadratic equation as an intersection of two functions, whereby at least one has to be quadratic. To determine the set of solutions the x-coordinate of the intersections  $S_1$  and  $S_2$  has to be considered.

#### Example:

$$-2x^2 = -8$$

$$f(x) = g(x)$$

$$\mathbb{L} = \{-2; 2\}$$

Figure 1: Graphical visualization of basic conception 1 (GV1)

**Basic conception 2:**

An equivalent transformation keeps the x-coordinate (the set of solutions) constant and simultaneous leads to a change of the functional value of the intersections.

Example:

$$\begin{aligned} -2x^2 &= -8 & f(x) &= g(x) \\ \Leftrightarrow -x^2 &= -4 & \Leftrightarrow h(x) &= i(x) \end{aligned}$$

**Figure 2: Graphical visualization of basic conception 2 (GV2)**

**Study design**

To evaluate if these normatively cited basic conceptions can be formed by students and hence can be proved empirically, special learning assignments have to be designed. Aim of the presented study is thus to develop a learning environment and subsequently to investigate if those basic conceptions can be formed by students. For this purpose, a teaching sequence of 2x45 minutes was designed. Both sets of 45 minutes dealt with one basic conception. Each set consists of a specially designed common starter with a subsequent individual working phase of 4 learning assignments. The utilized exercises in the working phase were supplementary designed with regard to a high potential of diagnosis implying a written response in addition to the actual task.

**Preliminary results and outlook**

A first postprocessing of students' solutions of the learning assignments revealed to evaluate the collected data quantitatively through a deductive procedure.

This leads with regard to the formation process of the first basic conceptions to the following preliminary results: The solution quote over the first 4 learning assignments amounts up to 81%.

In summary, it could be said, that the dealing with the exercises for the formation of the first basic conception (GV1) worked out well. Missing percentages are due to a lack of time, inaccurate drawing of graphs and mistakes in reading off exactly the relevant coordinates and distinguishing both from each other.

The evaluation of the learning assignments for the formation of the second basic conception (GV2) showed up to be more difficult. The used tasks were created too open and required for its processing the correct and precise use of mathematical language. These circumstances made the students' solutions difficult to evaluate. The tasks are now going to be revised more closely. The following study is going to be carried out once again, under the revisions of the exercises, this year.

## Provoking students to solve equations in a content-oriented fashion and not using routines by solving slightly modified standard tasks.

Simon Zell<sup>1</sup>

<sup>1</sup>University of Education Schwaebisch Gmuend, Schwaebisch Gmuend, Germany; simon.zell@ph-gmuend.de

*A lot of time in algebra lessons is spent on solving equations using routines. It is assumed that after many hours of training, these routines will be easily recalled and performed fluently. A study of 480 students in grade 10, which was undertaken at the beginning of a school year, showed that many students had forgotten these routines and were not able to reconstruct (alternative) solutions for simple equations. Content-oriented solving, which does not involve algorithms, is one way of helping students to solve equations using insight. Results from the same study indicate that this kind of problem solving can be promoted if standard tasks are modified slightly.*

*Keywords: Solving equations, content-oriented solving, concept of function.*

### Introduction

Students solve a great number of equations by using routines. Once a repertoire for these basic procedures has been established, a teacher can consider more challenging tasks in terms of solving equations. However, overemphasizing reproducing procedures monotonously can also be counterproductive (Arcavi, Drijvers, & Stacey, 2017). It may lead to making students inflexible when solving equations. If standard procedures are varied slightly, students cannot adapt the changes to the procedures they know. Solving tasks by routine and insight should be integrated. “In algebra teaching, therefore, procedures should be linked to an understanding of their meaning and to a flexible choice of solution methods; routine and insight go hand in hand and should be reconciled” (Arcavi, Drijvers, & Stacey, 2017, p. 92). Tasks should involve practising skills, but also address students’ thinking, alertness and creativity. Another approach which can support students’ thinking and alertness is solving tasks in a content-oriented fashion. It is a counterpart of solving tasks by routines. One example illustrates this way of solving. In the first week of semester, 30 beginning students of mathematics education were asked by the author to solve the equation  $(x - 2)^2 = -9$ . Everybody calculated the equation by expanding the brackets, using equivalence transformation and the quadratic formula. Finally, they came up that there is no solution. All of them have noticed the square and triggered the procedure to solve it by the formula. Nobody had taken a closer look at the equation and noticed that on the left side there was a square and on the right there was a negative number, therefore the equation had no solution. The alternative solution can be defined as a content-oriented approach. The algebraic structure was consciously analysed and theoretical knowledge about square numbers was applied. Analogous to the example above, solving  $1 - \frac{1}{x} = 0$  the routine way takes quite some time. Solving that equation content-oriented by analysing the structure, instead of just noticing an equation involving fractions can be much quicker and done with more understanding. A content-oriented way of solving could be: The difference has to be zero, therefore  $\frac{1}{x}$  must be one, therefore  $x$  is equals one. All these steps can be done by mental arithmetic. In both examples the content-oriented approach is the more insightful way of solving. Especially when solving equations students stick to

the routines. Promoting content-oriented solving of equations in class could break students' behaviour of using routines unrelatedly, and making them look at the equations given, using definitions or reflecting on methods already known and help them to solve equations with more understanding. Hence there is a need to find appropriate tasks or task assignments to enhance content-oriented solving.

## **Solving equations content-oriented**

Content-oriented solving is one part of a large framework that characterizes mathematical tasks in school. After analysing hundreds of mathematics lessons, Fanghaenel (1984) concluded that solving mathematical tasks in school should be organized in such a way that all students develop high mental activity by themselves as much as possible (p. 189). His detailed categorization of mathematical tasks has been used to analyse a great number of tasks in schoolbooks. One category describes a method for solving tasks. In addition to following routines, he distinguishes direct and indirect transfer of procedures and content-oriented solving (ibid., p. 98). Content-oriented solving (in German, *inhaltliches Lösen*) is realized if the person solving the task gains a clear understanding of the given situation by realizing characteristics and relationships, interpreting symbols and using theoretical knowledge, and then employs these to solve the given task. It stands in contrast to using routines, which are appropriate for solving a definite set of tasks.

Arcavi, Drijvers, and Stacey (2017) describe a class situation experienced by a teacher. After teaching 14-year-old students about quadratic equations, the equation  $(x - 3)^2 + 5 = 30$  was still on the board. The 12-year-old students entering the room for the next class could solve the equation without knowing the formal algorithms. They concluded that the number within the bracket had to be 25, therefore  $x = 8$  or  $x = -2$ . Whereas the 14-year-olds were struggling with the algebraic operations, the 12-year-olds were analysing the structure of the equation and making conclusions. This phenomenon can be explained by the concept of content-oriented solving. The 14-year-olds have had an introduction of formal procedures to solve quadratic equations. According to Fanghaenel (1984) they followed routines or have used a direct transfer, i.e. the equation is identified as a very similar task, which has been solved before and will be solved in the same way. The 12-year-old students couldn't do that, so they needed to apply theoretical knowledge. This way of solving can be identified as content-oriented, since they didn't know the procedure. If they do the same procedure several times, the solving behaviour can change from content-oriented to routine. Hence content-oriented solving depends on the reference field of a student and the tasks given, i.e. the same solution of a task can be seen as a routine or content-oriented, depending on a student's previous knowledge on solving the given task. Therefore tasks have to be chosen carefully to identify content-oriented solving in a written task.

Content-oriented solving is not the same as solving tasks semantically, although there are many commonalities. Kaput (1989) defines semantic actions or elaborations as ones that "are guided by the features of a reference field for the symbol system rather than by its syntax (using the syntax implicitly)" (p. 175). Content-oriented solving encompasses more than semantic approaches. Tasks that are asking for an interpretation of an object are semantic actions, but they do not require content-

oriented solving because only factual knowledge can be used. Tasks which require indirect transfer require semantic approaches and can be assigned to a semantic task.

Content-oriented solving of an equation occurs if students gain a clear concept of given preconditions and their deductions and consciously use these to determine a solution (Flade, Goldberg, and Mounnarath, 1992). A characteristic of solving equations that way is the use of heuristics (Rosin, 1984). Sill et al. (2010) characterize content-oriented solving as the solving of equations or inequalities without the use of routines. The regular use of this approach will continuously develop students' ability to identify term structures. Hence, they will become familiar with variables, terms and equations and tend to operate less with unknown symbols. Considering the variety of ways to solve a task content-oriented, it is likely that this type of solving will lead to a more comprehensive view of terms and equations.

The uses and objectives of content-oriented solving vary from lower grades to higher grades (Flade et al., 1992). Whereas in lower grades it can be applied to elementary equations, involving addition and multiplication, to help students in comprehending the elementary concepts of equations, it can be used at the upper secondary level to offer students creative approaches and allow them to solve mathematical tasks systematically and reflectively.

Seventh-grade students whose teachers promoted content-oriented solving even solved routines slightly better than students whose classes put more emphasis on routines (Fanghaenel, 1976). This result is remarkable because students in the experimental group had less time for practising routines and got slightly better results. However, the major effect of that study was seen in a test at the beginning of the following school year. In the control group (routines), results decreased significantly, whereas, in the experimental group (content-oriented), correct results increased. Emphasizing content-oriented solving led students to work out forgotten routines by themselves.

Such students, who have no formal knowledge of procedures, are forced to solve content-oriented. In elementary school, students are able to solve simple equations like  $18 - x = 13$  or  $3(x + 2) = 36$ . The first one can be solved content-oriented by trying out different values randomly or systematically or by asking oneself 'Which number subtracted from 18 will equal 13?' The second equation can be solved similarly by asking oneself 'Three times how much will be 36? 3 times 12 equals 36, therefore  $x$  must be 10'. Such students do not use an algorithm. They solve it by analysing the structure of the equation and using theoretical knowledge. The equation is solved with understanding because the given structure is analysed consciously. According to Fanghaenel's (1976) definition, content-oriented solving can also comprise (un)consciously reflecting on the possible procedures and choosing the most appropriate one. One result could be a student's decision to use a routine to solve a specific task. In that case, the essential difference to using routines is that a student (un)consciously analyses the given structure and reflects on possible approaches to solving a task.

In contrast to using routines, content-oriented solving enhances students' ability to create, combine, and vary mental images of mathematical structures. Therefore, this type of solving should be part of algebra lessons.

## How to implement content-oriented solving in class

Whenever a procedure is not yet known, students have to solve problems content-oriented (Fanghaenel, 1984). However, once routines are introduced, using a content-oriented approach can be ignored easily, as Freudenthal (1983) notes: “sources of insight can be clogged by automatism” (p. 469). To maintain student alertness when solving equations, unusual elements can be included in a set of exercises (Arcavi, et al., 2017). Another way to maintain content-oriented approaches is to lead students to constantly check every equation to be solved content-oriented (Sill et al., 2010). This method strongly relies on teachers’ patience and persistence. Hence, it is useful to find other ways to promote content-oriented solving that are more independent of teachers’ methodologies. To highlight the advantage of solving tasks content-oriented, all tasks need to be of the type that can be solved much more quickly in this way than by using a routine.

## Provoke students to solve content-oriented by suitable tasks

As part of a study to promote content-oriented solving, research questions included how well students were able to solve equations in that fashion and how the task assignment influenced students’ solving behaviour. For this study, a test was given at the beginning of the school year in September 2017. A total of 480 students in grade 10 at eight different Gymnasiums (schools for higher-skilled students) took part in the 45-minute test. The test included solving linear, quadratic, and exponential equations. All equations were set up with simple numbers and simple structures, i.e., they could be solved content-oriented by analysing the structure, using mental arithmetic and faster than using routines. Some of the items were written in a standard form, such as ‘solve the equation’, and other items were varied slightly.

All items were checked and validated in advance by members of the mathematics department at the University of Education Schwaebisch Gmuend and tested on 149 grade 10 students in nine classes at three different schools in January 2017 (Zell, 2017). As a result, small changes were made to two items and validated by interviews with students attending the University of Education. The coding of students’ solutions was differentiated in routine and content-oriented approaches. Within these categories it was distinguished into correct, incorrect and incomplete. Approaches, in which no routine or meaningful answer could be derived, were classified to other approaches. These categories were created by the author and cross-checked by members of the mathematics department and by the answers of the pre-test. Students are not given any instruction how to write down the solution. They were confronted with these tasks as in a regular testing. The first four tasks follow the familiar assignment “solve the equation”. Task 1c and 1d are slightly modified by not allowing the standard routine to force students solving these equations content-oriented.

Task 1: Determine the solution(s) of the following equations.

- a)  $x^2 + 4 = 0$
- b)  $2^{x+1} = 16$
- c) Determine the solution of  $3^{(x-2)} = 81$  without using logarithms.
- d) Determine the solution of  $2^{(x-2)} = -32$  without using logarithms.

The first two tasks can be solved by both routine and content-oriented. A students' solution was considered content-oriented, if he or she didn't follow the routine introduced in class. For tasks 1b-1d using/comparing the exponents to solve the equation was the expected content-oriented solution. This way was not mandatory taught in school and therefore considered content-oriented.

Task 2 had a modified assignment. Students had to give a reason for a statement. Because no concrete solution was demanded, there were more possible ways of solving each task. All tasks could be solved by using both routine and content-oriented approaches.

Task 2: Give a reason for these statements.

- a)  $2(x - 4) = 0$  has a positive solution.
- b)  $f(x) = x^2 + 2x + 1$  has no positive zeros.
- c)  $x^2 - 10x + 25 = 0$  has only one solution.

Hence, if the assignment of a task matters, the percentage of content-oriented approaches on these modified tasks should be considerably different.

## Results

The range of correct solutions is from 13.3% solving the equation  $2^{x-2} = -32$  to 63.1% solving  $2(x - 4) = 0$ . Students' answers for four tasks are shown in more detail. Looking at the results for Task 1a shows how using a routine dominated (see Table 1).

Task 1a: Determine the solution(s) of $x^2 + 4 = 0$				
Solved	correctly	incorrectly	incompletely	total
by routine (taking the square root)	32.5%	52.1%	0%	84.6%
Content-oriented (using term structure)	0.2%	0%	0%	0.2%
by writing down the solution without calculation	5.4%	0%	0%	5.4%
by using incorrect other approaches	0%	6.7%	0%	6.7%
nothing by giving no response	0%	0%	3.1%	3.1%

**Table 1: Types of solutions for Task 1a**

Only one out of 480 students solved it content-oriented by writing down an explanation. Twenty-six who just wrote down the solution might have solved it content-oriented. Because the test was done in a real classroom setting, some students might have copied their neighbour's answer. Consequently, only one student has solved that task content-oriented. Having a more open perspective, 5.6% solved the equation content-oriented. It is possible that they have seen the answer just by looking at the equation, like experts in mathematics do. Those students who solved the equation by using the square root tended to make mistakes. The most common mistakes were taking the square root of the left-hand side, which resulted in  $x + 2$ , or taking the square root of  $-4$ .

When solving Task 1b, only a small number of students remembered how to use logarithms to solve exponential equations (see Table 2). Because the numbers used in that task were simple, students had

the chance to solve it content-oriented by noticing that  $2^4$  is 16 and therefore  $x$  must be 3, or they could compare the exponents formally. These students who were able to take a content-oriented approach, tended to make less mistakes.

Task 1b: Determine the solution(s) of $2^{x+1} = 16$				
Solved	correctly	incorrectly	incompletely	total
by routine (using logarithm)	17.7%	6.6%	1.5%	25.8%
Content-oriented (looking at the exponents)	19.0%	3.1%	0.2%	22.3%
by writing down the solution without calculation	18.1%	0%	0%	18.1%
by using incorrect other approaches	0%	16.9%	0%	16.9%
nothing by giving no response	0%	0%	16.9%	16.9%

**Table 2: Types of solutions for Task 1b**

The equation structure in Task 1c is the same as in Task 1b, but using logarithms was not allowed. 54% of all students tried to look at the exponents, and 48.9% of them solved it correctly. Results in Task 1d are similar: 39.8% tried to solve it content-oriented, 13.3% of them correctly. Not allowing the standard procedure made the students to attempt solving the task content-oriented.

Task 2a contains a slight modification to the standard design ‘solve the equation’. Not asking for the solution, but instead, the reason why the solution must be positive, had an effect on students’ answers. Here, 27.9% of all students solved the task content-oriented, and 63.4% of these students did it correctly. 27.9 % is still a low percentage, but it is five times higher than the percentage that solved Task 1a content-oriented. Some examples of content-oriented solutions follow:

- “ $x$  must be positive, because having a negative solution, the result would be a negative value, because 4 is subtracted of  $x$ .”
- “Yes, because of product equals zero theorem: When multiplying one number with 0, the product is 0 as well; to attain 0,  $x$  must be 4, i.e. positive.”
- “ $2(4-4)=0$  has a positive solution, if  $x$  is greater than 4.”

Analysing the solutions to Task 2b (see Table 3), only 19.0% attempted to recall the formula on paper, and only 13.3% of them did so correctly. Only six students used the binomial formula, 23 students tried to solve it by considering parabolas, and 55 students used the term structure. The majority (51.2%) did not write anything down. Many students had forgotten the quadratic formula and were not able to reconstruct given knowledge to come up with a solution.

A small number of students used a content-oriented approach. Some examples will serve to exemplify the approaches used:

- “True, since the whole equation is an addition, the solution is always greater than 0, if one uses positive numbers.”
- “True, since using  $x = 0$ ,  $f(x)$  will be the result. All positive  $x$ -values are too large.”
- “There are no positive zeros because 1 is always added at the end of the equation.”

- “Because this function has a y-intercept of 1 and because the slope equals 2, it cannot have zeros in the positive section.”

Task 2b: Give a reason for this statement: $f(x) = x^2 + 2x + 1$ has no positive zeros.				
Solved	correctly	incorrectly	incompletely	total
by routine (formula for quadratic equations)	13.3%	5.7%	0%	19.0%
Content-oriented by using binomial	1.3%	0%	0%	1.3%
Content-oriented by using parabola	0.2%	3.5%	1.3%	5.0%
Content-oriented by using term structure	2.7%	5.2%	3.5%	11.4%
by using incorrect other approaches	0%	0%	14.6%	14.6%
nothing by giving no response	0%	0%	48.7%	48.7%

**Table 3: Types of solutions for Task 2b**

The content-oriented answers of tasks 2a and 2b show how a deep understanding of term structure can be promoted. Incorrect answers can show teachers what types of misconceptions the students have. Hence such tasks are very suitable for exercises recalling routines having been learnt long before. When discussing the students' solutions, not only are routines repeated but also content-oriented solutions. These solutions can show the meaning and properties of all the concepts involved. Students who have forgotten the routine needed also have a chance to find a solution.

## Conclusion

The results show that the content-oriented solving of equations is used by only a small minority of students. The more familiar a procedure is, the more routines dominate and alternative ways are less taken into consideration. But changing the tasks slightly has an effect on students' solutions, the percentage of content-oriented solutions increases. Hence, setting up tasks which contain easy numbers does not automatically make students consider alternative approaches. But adding features like asking for reasons, not demanding concrete solutions, forbidding routines on tasks and consciously using functions makes students solve equations content-oriented more frequently. As students' solving behaviour gets socialised during a longer time, regular implementation of such tasks may help students to consider content-oriented approaches more often.

Besides confronting students with unknown tasks (Fanghaenel, 1984) or make them trying to solve every equation content-oriented (Sill et al., 2010), slight modifications of standard tasks can promote this type of solving, too. The additional solutions are a fruitful element in a class discussion. So all students are able to see how equations can be solved in a different way and with more insight. These slight modifications can be created easily; therefore this approach to promoting content-oriented solving is a realizable one. Arcavi, et al.'s (2017) demand for more alertness and flexible use, when solving an equation, can be met by having such slightly modified tasks. When students are to solve similar tasks in the same content-oriented alternative, this approach might become a routine.

However, it is still better having students to choose between two routines than only having one. To prevent such behaviour, suitable tasks for content-oriented solving should be varied appropriately.

The aim of this paper is not to lower the importance of using routines. They are a necessary part of mathematics lessons. The intention is to break the dominance of using algorithms by helping students to be more reflective about a given structure and making them think about it. Then, when looking at an equation, instead of initially starting the routine, a(n) (unconscious) process of consideration of how to solve it appropriately might be initiated. Suitable tasks for content-oriented solving are a possible and a realisable way to reach that goal.

### Introduction

Around 25 participants attended the Thematic Working Group 4 sessions during CERME 11. 75% of them were Europeans, and the other 25% came from the Middle East or from Australia. Five discussion sessions were dedicated to specific topics (manipulation, artifacts, visualization, teacher education), and each contribution (in total 18 papers and 3 posters) was presented and discussed during 20 minutes. The last two sessions were dedicated to small-group debates that supported the writing of the final report that was presented on the final day of the conference.

The call for papers, the contributions, and the discussions, addressed classical issues in geometry education such as the role of manipulation, instruments, investigation and modeling, the ways of describing and training visualization processes or spatial skills, and the role of language in geometry, including problem solving, argumentation or proof. It appeared that the multiple frameworks or methods that helped in addressing these issues were sometimes very close, or sometimes shed different lights upon the phenomena we observed. In order to benefit from these multiple viewpoints, we decided that, rather than summarizing our work following each initial issue, we should identify general questions that reflected the heart of the discussions; these were:

- How is it possible to describe how space intervenes in “doing geometry”?
- What is at stake in learning geometry, from cognitive and didactical points of view?
- Which transversal competencies have to be taken into account in the teaching of geometry, and how are they interrelated?

The way we addressed these questions shows continuity in the group’s work across the CERME conferences. Schematically speaking, we could say that CERME 8 was more about what geometry is, CERME 9 about what is at stake when doing geometry, and CERME 10 about the various theoretical approaches of these questions. We built our discussion on this basis. We managed to address more efficiently these questions, and to understand better the similarity or complementarity of the participants’ points of view.

### Space in “doing geometry”

One of the toughest theoretical issues was about space, and the mutual understanding between psychology and mathematics education. We identified during CERME 11 that, on the one hand,

psychology considered that visualization was a part of “spatial skills” and that, on the other hand, to mathematics education spatial skills were a part of the visualization process. It seemed that this was not only a matter of word meaning, and we tried to investigate these opposite points of view.

We used the identification by Perrin & Godin (2018)<sup>1</sup> of three spaces involved in doing geometry: the physical one, the graphical one, and the geometrical<sup>2</sup> one (see Fig. 1). In a way, geometry consists in establishing relations between these spaces, and solving geometry problems needs to “grasp space” and to make the information usable in another kind of space.

Figure 1: three spaces involved in doing geometry, two points of view on it.

On the one hand, psychological points of view in the group (see Heil; Conceição) were mainly used in order to explore the articulation between physical and graphical space: How do children manage to represent physical space? What are the difficulties? How does it intervene in their solving physical space problems? This point of view put forth representational issue. Visualization is one of the ways to grasp and interpret information; then it is no more than one of the components of the spatial skills.

On the other hand, mathematics education traditionally focuses on the links between graphical and geometrical space. The main issue is the correct use of graphical information to elaborate concepts or to work on ideal objects, or the graphical representation of idealities (see previous TWG4 reports and Downton; Gridos; Jones; Palatnik). In this way, visualization also embraces geometrical knowledge or specific treatments of graphical space. Spatial skills are one of the treatments performed on the graphical space, so in this case they are just a part of visualization.

This clarification aims at improving mutual understanding, and then collaboration, not only by explaining the discrepancies but also by identifying complementary issues and showing that these points of view are in fact two sides of general matters about space.

<sup>1</sup> Perrin-Glorian, M.-J., & Godin, M. (to be published). Géométrie plane : pour une approche cohérente du début de l'école à la fin du collège. In proceedings of the CORFEM, *Ressources pour la formation des professeurs. Savoirs mathématiques à enseigner au collège et au lycée*. A preliminary version is available on <https://hal.archives-ouvertes.fr/hal-01660837v2/document>

<sup>2</sup> By geometrical space, we refer to ideal objects and their relations, which are mainly elaborated by/in discourse.

We can add that we do not pretend that the relations between physical and geometrical space are not relevant, and some of the works presented in the group examined it (Favilla, Luppi & Maschietto). They highlighted the potential of such direct geometrical interpretation of physical experience, including an instrumental point of view. In this case, though, neither visualization nor spatial skills are at the core of the studies.

## **Learning geometry**

The second main focus of our work was about “learning geometry”. It has to be noted that, even if specific learning topics were examined, the group discussions investigated how general competencies (such as creativity, flexibility, fluency, language, beliefs, etc.) may affect the learning of these specific topics (see Brunheira; Favilla; Gridos; Mendes; Palatnik). In this perspective, the role of everyday life, physical experience, manipulation or spatial skills in creating mental images or developing abstract concepts was more strongly highlighted than in the previous topic (Brunheira; Heil; Palatnik). The role of tools and artefacts was also discussed, highlighting, on the one hand, the limitation of their use (because of difficult instrumental genesis, but also for intrinsic reasons), and on the other hand, their potential, including higher education where it appears that tools, games, and manipulatives are very helpful but generally seen as something that is not needed (Bjørkås; Katter).

Language, and more specifically the emergence of geometrical lexicon, appeared as one great issue in the learning of geometry (Bulf, Favilla, Haj Yahya). Many contributions pointed out that constructing the meanings of the words used in geometry is a long and complex process that cannot be reduced to “vocabulary” issue. These meanings are the result of more general practices (including manipulation), negotiation, social interaction in problem solving contexts, combined to the cultural background – including everyday meaning that influences the understanding of the words. This dynamic and progressive learning of specific lexicon and meanings was coherent with the works on mathematical discourse, but it has to be noted that discourse itself was not studied in this case. This remains an open discussion field in this group.

It was connected to many contributions (Albano; Bernabeu; Brunheira; Gridos; Jones; Palatnik, Vieira da Silva) about argumentation, justification, reasoning or proving. This topic combined various levels of considerations, embracing the multiple facets of proof: required operation for proving in geometry (such as the analysis of figures as components and relations), relations between arguing, reasoning and justifying, or about the specific writing process that is required by formal proof. One contribution proposed a general overview, showing variations of the type of language used during the proving process.

## **Teaching geometry and teacher education**

These two issues have been unified into one only discussion group, as many contributions addressed general topics, relevant for both of them. The participants raised four great topics involved in the teaching of geometry: problem solving, manipulation with tools (including drawings), visualization, and proof (see Fig. 2). Language has been added considering some contributions showing how it is linked to manipulation with tools and to visualization.

Some contributions used these topics to analyze precisely the pre-service and in-service teachers' geometrical knowledge, focusing on specific parts of the diagram we propose (Brunheira; Bulf; Nechache; Haj Yahya; Mendes). It has to be noted that the contributions mixed analysis about specific, local, geometrical knowledge, and more general concerns as described in Fig.2, in a very convincing way.

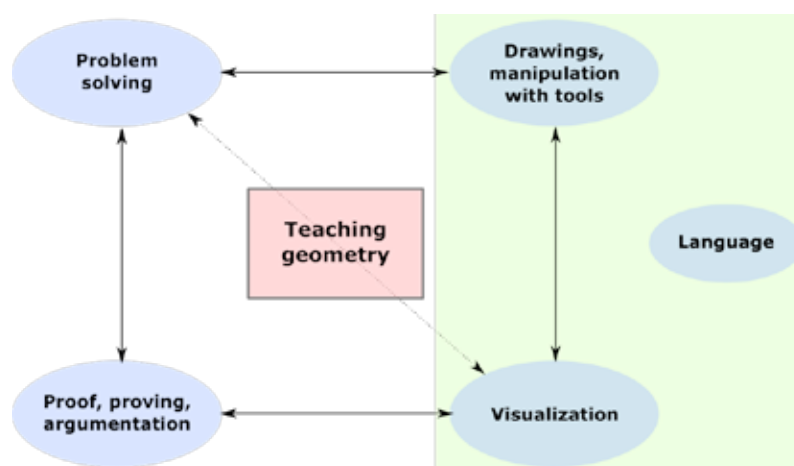

Figure 2. Topics involved in teaching geometry and teacher education

Other contributions proposed results about the relations between these topics (Bjorkas; Boavida; Bulf; Delgado; Mendes; Palatnik). The proving process needs the pupils to identify relations in the drawings, so both manipulation and visualization should be considered in the teaching of proof, and in the teacher training curricula. Moreover, by using specific artifacts (e.g. geoboard), by promoting specific strategies or by giving access to multiple solutions of a single problem, teachers promote efficient manipulation and visualization and, consequently, support solving problems skills development and the understanding of geometrical concepts. Then, teaching sequence design may take into account the relations we indicated in the diagram, and the difficulty to coordinate multiple poles of geometrical activity that was raised by some contributions, and by previous works in the group (e.g. about Geometrical Working Space or language). In a general way, this indicates that neither teaching nor teacher training should be only focused on mathematical contents or on a specific pole, but it should embrace the coordination between many of these poles.

Ultimately, we would like to mention that these general components involved in the teaching of geometry were less intertwined with specific topics, and then were helpful when examining how interactions with other fields (such as arts education) may be productive.

## Perspectives and conclusion

As is clear in the papers that follow this introduction, the participants contributed to enrich the understanding of some classical issues in geometry education, and to develop more topical ones. We hope that a careful reading of these papers may also reflect that the work and the discussions promoted mutual understanding about both the frameworks and the issues they address. This seemed to be more productive than seeking a unified and unique framework, and we believe this to be a major contribution of CERME in general, to be continued over the next sessions of the group.

# A computer-based environment for argumenting and proving in geometry

*In this paper, we face the issue of argument and proving in geometry. Overcoming difficulties encountered by the students when moving from argumentation to proof may require suitable didactical interventions. Our contribution to research concerns the design of a specific computer-based didactic environment. We report how 14-15 years old students from high school conjecture and prove within the designed environment and we discuss the preliminary findings.*

*Keywords: Geometry, argumentation, technology integration, design.*

## Introduction and theoretical framework

For what geometry concerns, Sinclair, Bartolini Bussi, Villiers, Jones, Kortenkamp, Leung, & Owens (2016), among main strands of contributions to the geometry education they found in reviewing the literature since 2008, identified in particular the understanding of the teaching and learning of definitions and of the proving process. Geometry theorems are a logical consequence derived from an available theory, that is from a set of axioms, theorems previously validated, and definitions, necessary to avoid logical circularity (Fujita, Jones, & Miyazaki, 2018). As reported in the survey by Sinclair et al. (2016), one of the major threads in geometry education concerns understanding of the teaching and learning of definitions, in particular for triangle and quadrilateral.

Definitions comes into play when the students try to construct mathematical proofs, meant as “logical sequence of implications that derive the theoretical validity of a statement” (Mariotti, 2006, p. 182). Moore (1994) highlights that students do not necessarily understand the content of the definitions and how to use them (Moore, 1994).

Boero, Garuti and Mariotti (1996), while not denying the distance between argument and proof, do not consider it an obstacle. Researchers, in fact, highlight a continuity between argument and proof, called cognitive unity. During the problem solving process, argumentative activity usually produces a conjecture. The hypothesis underlying the concept of cognitive unity is that there is a continuity between the argument produced and the proof, which means that the argument can be used by the student in the construction of the proof, reorganizing it appropriately according to a logical scheme. In this sense, open problems (Arsac, Germain, & Mante, 1991), which require conjecture for their resolution, appear to be extremely effective in introducing the concept of proof, as the proofing process is favored by the argumentative one (Boero et al., 1996). However, the analysis of cognitive unity does not cover all aspects of the relationship between argument and proof. Pedemonte (2007) points out that cognitive unity does not take into account the structural continuity between argumentation and proof, when the inferences in argumentation and proof are linked together through the same structure (abduction, induction or deduction) (Pedemonte, 2007).

Difficulties can arise when moving from argumentation to proof, as it requires radical changes in the structure, such as moving from abductive to deductive structures. Facing such difficulties and overcoming them constitute an education goal that may require specific didactical interventions.

Our research study intends to contribute to this issue with the design and the experimentation of a specific didactic environment.

## The experimental design

In the following, we are describing the experiment. The aim is to explore the educational potential of a certain working environment with respect to the process of producing conjecture and proving it. The setting of the environment have brought to identify three types of working environment that can be combined. In each of them we tried to create elements that would implement certain hypotheses, based on the theoretical framework.

*Hypothesis 1.* The use of open problems, i.e. problems where conjecturing is required. This is consistent with various studies (Arsac et al., 1991; Boero, Garuti, & Lemut, 1999; Hadas, HersHKowitz, & Schwarz, 2000; Pedemonte, 2008).

*Hypothesis 2.* The shift from spontaneous arguments - arisen during and/or after the process of producing a certain conjecture - to the proof may present some difficulties both in terms of reference system and in terms of structure. The formalization environment has been designed to provide support with respect to the expected difficulties. This latter hypothesis is consistent with the results of different studies based on the notion of cognitive unity (Pedemonte, 2002, 2007)

*Hypothesis 3.* The importance of exploratory talk in collaborative situations is crucial for improving the rise of conjectures and their formalization. This fits the dialogic approach in collective geometrical thinking (Fujita, Doney, & Wegerif, 2017). That is why the design foresees to alternate individual and social tasks where students act “as critical friends”.

The aim of our research study is that of exploring the educational potentialities of a computer-based environment with respect to support students in solving a conjecturing open problem, and subsequently providing a proof of the conjecture. According to the Hypotheses, a computer-based environment was designed offering an organized environment where students work alone and with peers for solving conjecturing problems, producing conjectures and their justifications and formal proofs.

In the following, we describe the main components of the computer-based environment, together with the rationale of their design, and an overview of the methodology; then we present some preliminary findings concerning only one of the three experimental settings.

### The computer-based environment

According to Hypothesis 1 we selected a conjecturing problem:

*Given a parallelogram ABCD, draw a parallel to the diagonal BD passing through one of the other vertices. Extend one of the sides of the parallelogram that does not contain that vertex until it meets the drawn parallel. Which quadrilaterals can be identified in this figure? What kind are they? Please justify your statements.*

The student is required to construct the figure, following the given instructions, then to answer to the posed question concerning the identification of specific quadrilaterals and justify her conjectures. Starting from the parallelogram ABCD and drawing the parallel to BD through A, two different figures can arise: the first one obtained by extending the side BC (Figure 1.a) and the second one by extending the CD side (Figure 1.b).

The mathematical theory related to this problem concerns the definition of parallelogram, trapezoid and rectangle. It is expected that the students recognize the characteristics of a certain figure and use the definition in the direction that allows to derive the name of the figure from its characteristics.

Figure 1: Two possible constructions

The computer-based working environment consists of three working spaces: *Working alone*, *Working with others* and *Assessing the others*, composed of various tasks, some individual and others social. In individual tasks the student does not communicate with her teammates and answers the proposed question herself. In social tasks the student answers individually but discusses with teammates in a forum (Figure 2). The computer-based working environment so designed exploits the potential of the Moodle platform in terms of built-in resources (Questions and Answers Forum, GeoGebra Task, Chat) and of integration of new digital applications (such as ISQ), together with the overcoming of space-time constraints. This allows the design of new activities, inconceivable without the use of the technology - level of Redefinition in the SAMR model (Romrell et al., 2014). Moreover, the automatic reports of the platform allow the teacher to take advantages of an augmented reality for what concerns the students' actions and thinking.

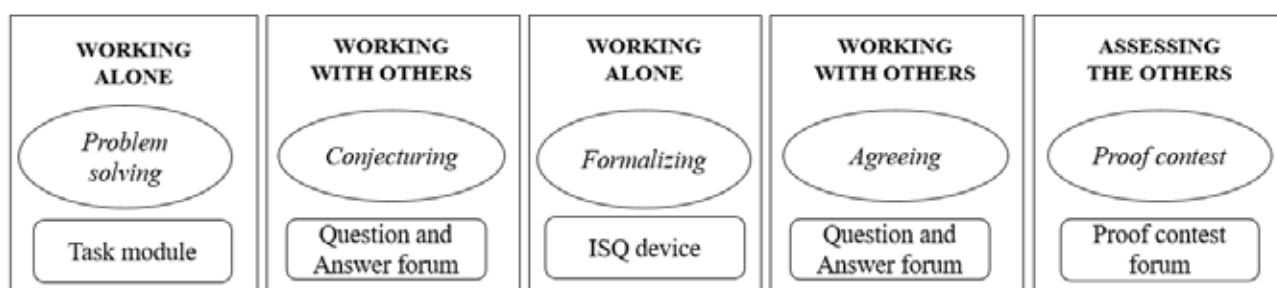

Figure 2: the design of the learning activity

We are detailing only the *Working alone* environment, on which we focus in this paper. It consists only of individual tasks, more precisely, the following two individual tasks:

- *Problem solving*: the student is asked to face the above problem. She is equipped with a “blank” GeoGebra page, predefined by the teacher/designer., suitably customized in order to show only the needed GeoGebra commands. The student submits her answer, consisting in: i) a figure constructed according to the given instructions, in particular the student is required to name the vertices fitting such instructions; ii) the identification of the quadrilaterals; iii) the justification of such identification. Using the Moodle *Task* module, the figure related to her GeoGebra construction is attached as the ggb file and the answer is given as a plain text in a blank box.
- *Formalizing*: the student is required to prove her conjectures reorganizing the justifications previously given according to a logical scheme. At beginning, the student is asked to choose one of the two figures shown in Figure 1, if it is the same of the one she constructed, or if it is not the case, she is required to upload her own ggb file. Therefore, starting from her own construction, for each quadrilateral identified, she is expected to prove her statements rearranging her own arguments into a logical chain. Such formalization is supported by a device consisting in a GeoGebra application, called ISQ (Interactive Semi-open Question), integrated into Moodle. It consists of digital language tiles that can be drag and juxtaposed in order to construct a sentence that represents the answer to a given question (Albano & Dello Iacono, 2018). In this case the ISQ has been enriched by some

fixed digital tiles constituting some kind of “Bank of Theory” which contains definitions, properties, theorems that are useful for proving the mathematical concepts at stake. In our case it contains only the definitions of parallelogram, trapezoid and rectangle. We have chosen to write the definitions, distinguishing explicitly between the two directions of the equivalence. This choice aims to make students aware of the existence of the two directions and of the fact that sometimes it is useful to use one direction and sometimes the other direction (Figure 3). For consistency, we always used the formulation “If ... then” and in particular indicated with Def #a the direction “If DEF then PROPERTY” and with Def #b the direction “If PROPERTY then DEF”. The construct “If ... then...” has been implemented as “PROPERTY  $\Rightarrow$  DEF” and “DEF  $\Rightarrow$  PROPERTY”. Concerning the digital tiles, we have chosen to merge the verb “to be” to the next adjective if it has the meaning of “to have the property of” (e.g. “is isosceles” is equivalent to saying “has the property of being isosceles”). Moreover, causal conjunctions constitute digital tiles in themselves to highlight the causal structure.

<b>DEFINITION OF PARALLELOGRAM</b> Def. 1a: A quadrilateral is a parallelogram $\Rightarrow$ it has the opposite sides parallel Def. 1b: A quadrilateral has the opposite sides parallel $\Rightarrow$ it is a parallelogram				
<b>DEFINITION OF TRAPEZOID</b> Def. 2a: A quadrilateral is a trapezoid $\Rightarrow$ it has two parallel sides Def. 2b: A quadrilateral has two parallel sides $\Rightarrow$ it is a trapezoid

in fact	then	because	by	and

Figure 3: ISQ in the Formalizing task

The ISQ contains several overlapped copies of each digital tiles, in order to let using the same tile several times. The available digital tiles allow to build various sentences that can be correct or not correct as well as complete or incomplete answers. The digital tiles, labelled with Def #, allow the production of sentences recalling definitions reported in the Bank of Theory (see on the left of Figure 3).

### The methodology

We assume a design based approach with the intention to develop an artifact, i.e. the learning computer-based environment including new developed digital application such as ISQ, which is supposed to be optimized according to the findings of performed empirical studies.

In order to analyze the contribution of the various components of the computer-based environment, we decided to draw three different experimental settings:

- 1) a setting without collaboration but with the support of ISQ, i.e. *Working alone*, to understand the actual contribution of this ISQ device;
- 2) another setting in which students can collaborate with each other, but without the support of ISQ, i.e. *Working with others*, to understand the actual contribution of collaboration;
- 3) the complete setting, with the possibility for students to be supported in the individual phase by the ISQ and, subsequently, to collaborate with each other, so as to be able to observe the contribution of the toolkit and of the collaboration at the same time.

The experimentation involved 72 9th-10th grade students from two different scientific high schools, distributed into the above experimental settings according to the random choice of the teacher. All

the data have been collected by means of the platform's reports and they have been analysed from a qualitative point of view.

In this paper we focus on the setting *Working alone*, for investigating what the ISQ device shows about the students' way of reasoning. To this aim, we have compared the students' transcripts before and after the use of the ISQ device.

## Preliminary findings

In this paper we focus on the ISQ device and its functioning within the Working alone setting. We report the analysis of the data and report some findings.

The analysis of the data shows interesting relationships between freely expressed arguments and the corresponding formalized arguments, organized through the use of the predefined digital tiles.

We will discuss in more details the outcomes of three students: Fromix, Antonio and Denisa. For each of them we are considering the figures they freely constructed by GeoGebra (first) and chose among the available (then) and their answer to the question posed by the given problem, in an open-answer mode (first) and by the digital tiles offered by the ISQ (then).

Let us analyze the answer produced by Fromix. He attaches the following GeoGebra figure:

Figure 4: Fromix's GeoGebra construction

and writes the following in the available blank box of the Moodle Task module:

- 1 Fromix: We can highlight as many as 3 figures:
- 2 ABCD : that is the given parallelogram.
- 3 DBCI : another parallelogram, since it has pairs of sides congruent and parallel and we can also notice one of its 2 diagonals (DC).
- 4 AEBC : scalene trapezoid having a longer base parallel to the smaller one and 2 not congruent sides.

Then, Fromix chooses the Figure 1.b and, using the digital tiles (highlighted by grey background) provided by the ISQ, writes the following sentences:

- 5 Fromix: A E B C is a trapezoid by hypothesis because it has two parallel sides
- 6 A B C D is a parallelogram because it has the opposite parallel sides so by Def. 1a
- 7 D B C E is a parallelogram because it has two opposite parallel sides so by Def. 1a

Fromix individuates three quadrilaterals that he classifies as two parallelograms and a trapezoid according to their properties.

We can note that Fromix, moving into the Formalizing task through the use of the digital tiles, does not literally translate the statements freely produced. Some properties that appeared in the first

expressions are neglected, whilst the reference to the definition emerges. According to our hypotheses, the availability of specific digital tiles seems to have determined a shift of attention on the characterizing properties, that is having two parallel sides (row 5), disregarding the presence of two non-congruent sides (row 4). Fromix does not make explicit reference to the digital tiles of the definition of trapezoid. Thus we can interpret this phenomenon as a contribution of the ISQ device that induces the student to analyze the content of the definitions. However, the formalized version is not logically consistent: as matter of fact, it seems that she uses the definition 1a to derive the parallelism of the opposite sides.

Let us analyze the answer produced by Antonio. He attaches the following GeoGebra figure:

Figure 5: Antonio's GeoGebra construction

and writes the following in the available blank box of the Moodle Task module:

- 8 Antonio: In this figure it is possible to identify the following quadrilaterals: ABCD, BCED, ABCE.
- 9 The quadrilaterals ABCD and BCED are two parallelograms because the opposite sides (AB, CD- BC, AD-DB, CE-CB,DE) are parallel,
- 10 while the quadrilateral ABCE is a trapezoid because it has two parallel sides (AE,CB) and two opposite oblique sides (AB, CE).

Then, Antonio chooses the Figure 1.a and, using the digital tiles provided by the ISQ, writes:

- 11 Antonio: A B C D is a parallelogram by Def. 1.a
- 12 E A D B is a parallelogram by Def. 1.a
- 13 A D C E is a trapezoid because it has parallel opposite sides

We can see that Antonio, using the digital tiles, makes explicit reference to the definition of parallelogram given in the ISQ (rows 11 and 12). Anyway, switching from the free formulation to the one supported by the digital tiles, he loses one step of the argument and it remains unclear how the definition is used, i.e. which are the observed parallel sides needed to apply the definition (row 9), although the digital tiles would have been available to do that. On the contrary, comparing row 10 and 13, we can observe that the characterizing property is expressed but the reference to the definition is missing. Moreover, in any case, moving from the free expression to the formalization, any reference to the specific figure is lost. As in the case of Fromix, we can notice again that the ISQ device seems to divert attention from the non-parallel sides of the trapezium (row 10 and 13).

Let us analyze the answer produced by Denisa. She attaches the following GeoGebra figure:

Figure 6: Denisa's GeoGebra construction

and writes the following in the available blank box of the Moodle Task module:

- 14 Denisa: In the figure there are two parallelograms,  
 15 because by constructing the parallel to the diagonal BD and extending the side, we have the intersection of the two lines to form another triangle equivalent to half of the initial parallelogram.

Denisa uploads her own figure and, using the ISQ, writes the following sentences:

- 16 Denisa: A B C D is a parallelogram by Def. 1.a it has parallel opposite sides  
 17 B E C D is a parallelogram by Def. 1.a it has parallel opposite sides  
 18 A B C E is a trapezoid by Def. 2.a it has parallel opposite sides

In the free answer environment Denisa individuates two quadrilaterals, that she identifies as two parallelograms, providing a justification referring to the construction made.

In Denisa's case the change from the free response version and the ISQ-driven version is more evident than in the other cases. First of all, she notices a third figure (a trapezoid) who had not initially identified (rows 18). Furthermore, in the free answer she does not differentiate the two parallelograms and does not provide any real argument to justify the classification, just repeating the construction commands. On the contrary, in the ISQ-driven version, she names the parallelograms and provides arguments referring both to definitions and to the properties (rows 16-17-18). Similarly to Fromix, the use of definition is not logically consistent.

## Discussion and conclusions

The previous analysis points out the influence of the ISQ device on the transition from the free expression to the formalized expression, as a matter of fact we can notice a change which highlights interesting elements. On the one hand, the students focus and select the relevant properties, neglecting the others ones, not distinctive. This can be interpreted as due to the availability of the definitions' formulation that shows only the distinctive properties. On the other, formalization is not a simple transcription but it implies a "logical" interpretation of what is expressed in natural language and a transcription of that interpretation into the language using the digital tiles and in particular the connective " $\Rightarrow$ ". Here we can observe how the interpretation of why as explanation is translated by the connective " $\Rightarrow$ ", even if this translation is not consistent with the formal language. What appears is the fact that all students (not only the ones reported above), in the transition to the use of digital tiles, use the wrong direction of the definition. It would seem that they interpret the symbol " $\Rightarrow$ " according to the verbal structure used in the free formulation of the answer. More precisely, comparing the free explanations, it would seem that they reproduce the verbal structure "FIGURE is X because Y" as "FIGURE is X  $\Rightarrow$  Y". that is, they replace "because" with " $\Rightarrow$ ", so that in the argument the premise follows the claim.

We want to underline that the logically correct use of the sign “ $\Rightarrow$ ” is not spontaneous, nor the transition from the use of “because” in informal language to the use of “ $\Rightarrow$ ” in formal language. The fact that the ISQ device makes evident such difficulty allows the teachers to identify such kind of obstacle and to intervene opening a discussion on the mathematical meaning of definitions.

### Acknowledgment

We thank the teachers Carlo Celoro and Antonella Maffei of the IISS “Umberto Nobile – Roald Amundsen”, Lauro (Italy), and their students, who participated to the experimentation.

*We conducted a teaching experiment of ten lessons with third-grade students (9-years-olds) to analyse the evolving understanding of the relationships among geometrical shapes. In the teaching experiment, pupils recognized, described, represented, built and classified two-dimensional figures. Analysis of pre-/post assessments showed some changes in students reasoning about how they began making sense of the relationships among the geometrical shapes. However, the use of formal definitions of geometrical shapes constituted a challenge for students since they imposed linguistics conditions to how the relationships among figures could be established. The results show that understanding the relationships among geometrical shapes is a slow process and depends on the logical terms used in the formal definitions.*

*Keywords: Geometrical thinking, primary school, geometrical shapes, relationships among geometrical figures.*

### Introduction

Students develop the comprehension of geometrical figures in a progressive way, initially, they recognise the figures by perceptual similarity, continue with the recognition of attributes and finally they base their thinking on concept based on the definition (Satlow & Newcombe, 1998). Recognizing attributes and relating them to make classifications is considered a relevant aspect in the development of geometrical thinking (Clements, Swaminathan, Hannibal, & Sarama, 1999; Elia & Gagatsis, 2003; Levenson, Tirosh, & Psamir, 2011). Classification of geometrical shapes, links to definition and the analyse of attributes of different geometrical shapes to distinguish between critical and non-critical attributes. Classification process can be hierarchical or partitive (de Villiers, 1994; de Villiers, Govender, & Patterson, 2009).

By the term hierarchical classification is meant here the classification of a set of concepts in such a manner that more particular concepts form subsets of the more general concepts. [...] In contrast to a hierarchical classification there also exists the possibility of a partition classification of concepts. In such a classification however, the various subsets of concepts are considered to be disjoint from one another (de Villier, 1994, p. 11–12).

It has been shown that students have difficulties in the transition from the recognition of the attributes and distinguish critical and non-critical aspects to perform classifications, especially hierarchical classifications of the quadrilaterals (Bernabeu, Moreno, & Llinares, 2018; Erez & Yerushalmy, 2006; Gal & Linchevski, 2010; Jones 2000). To try to better understand this transition in students' primary school, we investigated third-grade students' evolving understanding of the relationships among geometrical shapes, especially to know how pupils understand geometrical figures and establish

relationships among these geometrical figures, that is, consider whether a geometrical figure belongs or no to a figure class.

## **Theoretical perspectives**

### **The relationship between levels of geometrical thinking and figure comprehension**

According to Van Hiele's theory (Clements & Battista, 1992; Battista, 2007), the development of students' geometrical thinking is divided into progressive levels. The first three levels describe the process up to the comprehension of relationships among geometrical shapes:

- Level 1: Visual. Students identify the figures in relation to their appearance. To recognize figures, they do so through familiar prototypes (e.g. saying that a rectangle "looks like a door"). They are not aware of the properties of geometrical figures. The reasoning of students is dominated by perception.
- Level 2: Analytic/Componential (Battista, 2007). Students identify shapes according to their properties and they can characterize the figures by their attributes. Battista (2007) refined this level proposing three sub-levels. He theorized that students begin with "visual-informal componential reasoning" where they begin to focus on parts of shapes and doing visual, informal and imprecise descriptions. Pupils advance to "informal and insufficient-formal componential reasoning" where they use formal terms and informal descriptions, but they make definitions with unnecessary attributes. Occasionally, students advance to "sufficient formal property-based reasoning" where they make descriptions with formal geometrical terms for all the properties of the geometrical figures. The change from insufficient to sufficient definitions is a gradual shift from seeing the figures as a whole to focusing on the parts of these to see the figure as a coherent structure (Pegg & Davey, 1998).
- Level 3: Abstract/Relational. Students identify relationships among shapes and give informal arguments to justify their classifications (e.g., a square is a special type of parallelogram). They can discover properties of kinds of figures by informal deduction. Therefore, it is considered that the hierarchical classification is at this level.

### **The dual nature of geometrical figures**

Tall and Vinner (1981) developed the ideas of concept image and concept definition. Concept image is used to describe, "the total cognitive structure that is associated with the concept, which includes all the mental images, properties, and associated processes" (Tall & Vinner, 1981, p.152). Concept image may include images that are inappropriate and contradict the definition of the concept (Hershkowitz, Bruckheimer, & Vinner, 1987; Vinner, 1991; Levenson et al., 2011). On the other hand, concept definition is "a discursive description to specify that concept" (Tall & Vinner, 1981, page 152) accepted by the mathematical community. One relevant aspect in the relationship between concept image and concept definition is to become to recognize the attributes of the definition as a sufficient condition. This dual nature of geometrical shapes in which concept and image are interrelated is underlined by the notion of "figural concept" (Fischbein, 1993).

In the understanding of this dual nature of geometrical figures, the sufficient conditions to recognize or to represent examples of geometrical shapes can be revealed by the transformations among various

semiotic representations. Duval (1995a, 1999) indicates how his theory of registers of semiotic representation can be used as a tool to analyse the cognitive processes through which pupils develop the geometrical thinking. Duval (2017) indicates that we can analyse the students' productions in terms of registers regarding the coordination between different apprehensions: perceptual, discursive and operative. Perceptual apprehension is the ability to recognize a figure in a global way; the discursive apprehension is the ability to link mathematical properties with the parts of the figure; and operational apprehension is the ability to modify or construct a figure to solve the task (change orientation, decompose it). Duval (1995b, 2006) defined two of such transformations: Treatment and Conversion. Treatments are transformations of representations that happen within the same register: for example, completing a figure using perceptual criteria of connectivity or symmetry. Conversions consist of transformations of representations from one register to another (such as from the visual register to the discursive one), without changing the objects that denote. The association of a figure with mathematical statements, can be done in both directions: from the visual to the discursive (from the figure to the definition) and from the discursive to the visual (from the definition to recognize the geometrical figure) (Duval, 1995b). This translation is the one that allows linking the process of defining a geometrical figure giving a minimum set of relevant attributes. However, there are no descriptors of the cognitive processes through which students develop the geometrical thinking. Therefore, we propose to identify descriptors of the development of geometrical thinking about geometrical figures in 9-year-old pupils, and specifically,

- How students understand geometrical figures and,
- How reasoning about the relationships among them?

## Method

### Context

Participants were fifty-nine third-grade pupils (9-years-old) from an elementary school located in an area of average socioeconomic status in Spain. This study was conducted as a teaching experiment designed to allow pupils establish relationships among geometrical shapes. A researcher of the research group performed the role of the teacher in both classes during the instruction.

### Teaching experiment

In each class, we carried out ten sessions, two per week from May to June during the academic year 2017-2018. Pupils were asked for: recognizing and analysing attributes of different shapes, identifying critical and non-critical attributes, establishing relationships between attributes of shapes. They also had to represent and/or construct the shapes according to the given conditions or classify attending to criteria. Contents used during all sessions are shown in Table 1.

First week	First session. Polygon attributes: closed, straight and non-intersecting sides. Polygons according to the number of sides	Second session. Diagonals. Concave and convex polygons
Second week	Third session. Symmetry axis. Symmetrical figures	Fourth session. Acute, right and obtuse angle

Third week	Fifth session. Types of triangles according to their sides: equilateral, isosceles and scalene triangle. Hierarchical relations: the equilateral is an isosceles	Sixth session. Types of triangles according to their angles: acute, right and obtuse triangle
Fourth week	Seventh session. Types of triangles according to their sides and angles	Eighth session. Types of lines: parallel and non-parallel. Types of quadrilaterals: parallelograms, trapezes and trapezoids
Fifth week	Ninth session. Types of parallelograms: square, rhombus, rectangle and rhomboid. Hierarchical relations: the square is a rhombus, and the square is a rectangle	Tenth session. Properties of parallelograms: equal opposite sides and angles; diagonals cut in half

**Table 1. Conceptual characteristics of the sessions of the Teaching Experiment**

During the sessions, pupils built different shapes with resources such as *mecano* or geoboard. For working the classification tasks, we used digital board, so students could share their resolution with the whole group. Next, students individually solved other tasks. We used hierarchical definitions. For example, we defined the isosceles triangle as a triangle with two equal sides. In this case, we consider that an equilateral triangle is an isosceles triangle since it has two equal sides. Furthermore, we defined a trapezium as a quadrilateral with one pair of parallel sides. In this case, a parallelogram is a trapezium (British version) (Fujita & Jones, 2007).

For this report, data come from the initial and the final test. The aim was to get evidences about pupils' understanding of geometrical figures. Students' answers were codified and agreed by the research group. For the analysis of the data and the creation of the scheme of emergent codes that we generate from the answers of the students, we rely on van Hiele levels (Clements & Battista, 1992; Battista, 2007); Duval's theory (1995a, 1995b, 1999) that considers the transformations of the registers and the coordination of the apprehensions, the relationships between image concept and definition concept (Tall & Vinner, 1981), and the way that geometrical figures were related (to classify a shape in different ways and label it with different names) (Erez & Yerushalmy, 2006).

## Results

### The code schemes

The emergent coding scheme changed to accommodate the features that pupils included in their work and regarding the specificity of the tasks (Table 2). We compared the responses to the initial and final test and developed the emergent coded schemes as follow:

- *Students identified geometrical figures by their appearance*: what that it means that the recognition of geometrical figures is purely perceptual. For example, concerning to task 5: "It is a normal and ordinary triangle"; "The same figure as the " figure a"; "All the figures are triangular"; and in the Task 6: "Yes, because it is the same".
- *Students recognized some attributes of geometrical figures without establishing relationships among attributes that define the general set*: that it, students could recognize some attributes

of geometrical figures as number of sides, names of figures or types of figures, but they still made mistakes when they related them to its definition and perform relationships among geometrical figures. The apprehensions are not still coordinated correctly. For example, in task 5: “It has three vertices”; “It is a triangle”; and in task 6: “It has four sides”; “It is a square”.

- *Students were able to establish relationships among figures by recognizing that a figure belonged to a general set.* That is it, pupils related the definition to the parts of plane shapes to realize relationships (hierarchical and partitive relations). They began to coordinate the apprehensions. For example, in the hierarchical relation, concerning to task 5: “Yes, because an equilateral is an isosceles” and in task 6: “Yes, because at least has 2 parallel sides”. Conversely, regarding partitive relation, in task 5 a pupil said: “No, because an equilateral is not an isosceles” and in task 6 another said: “No, because it has all parallel sides” (not including the parallelogram as a trapezium).

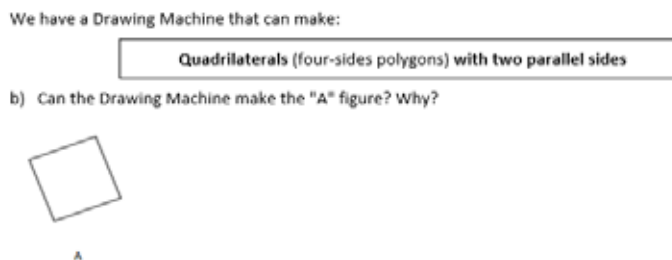

### Initial and Final test: Progression of thinking about relationships among geometrical shapes

To report the progress of the understanding of plane geometrical figures, we present the answers to two tasks from the initial and final test. In both tasks we had a "Drawing Machine" that could make a set of figures with common conditions (Battista, 2012). In one task, we provided a set of isosceles triangles (a triangle with two sides equals) that the machine could make and a set of scalene triangles (triangles with the three sides different) that the machine could not make. The question was that if the Drawing Machine (Figure 1) could draw an equilateral triangle (visual example).

**Figure 1. Figures of Triangles in the Task 5**

In another task, a verbal description of the shape was given: The Drawing Machine can make “quadrilaterals (polygon with four-sided) with two parallel sides” and it was asked if the parallelogram (square) (visual example) could be made by the machine (Figure 2).

**Figure 2. Figure of Quadrilateral in the Task 6**

These tasks tried to show how students establish relationships among figures and use the logical relationships among the attributes identified in the figure. In this paper, we present the frequencies of

codes of both tasks (118 answers, that is, 59 of each task) that reflect the progress from perceptual to analytic recognition, and the initial understanding of the relationships among figures (Table 2). The frequency of the students' answers has shown a development in the reasoning of elementary school pupils about geometrical figures and it has also shown how they reason about the relationships among these figures.

Codes (n=118)		Initial-Test	Final-Test
1. Students identify the figures in relation to their appearance		26 (22%)	12 (10%)
2. Recognize some attributes of geometrical figures (but without established relationships with attributes that define the general set)		28 (24%)	48 (41%)
3. The relationship among figures (recognize a figure belong to a general set)	3.1. Recognize the attribute defines the set (recognize hierarchical relationship)	10 (8%)	26 (22%)
	3.2. Recognize the only partitive relationship	2 (2%)	7 (6%)
4. Others (meaningless or blank answers)		52 (44%)	25 (21%)

**Table 2. Frequency of codes**

### **The development of the understanding of geometrical figures**

Analysis of data has shown that students have modified their way of reasoning from the initial test to the final. First, the purely perceptual recognition decreased from 22% to 10% after the teaching experiment. Also, the recognition of attributes in the figures presented in both tests increased from 24% to 41%. On the other hand, concerning the relationships among geometrical figures, it has been possible to verify how in the final tests, these relationships have been accentuated, since in the hierarchical relations had 8% in the initial test, and this rose to 22% in the final test. Regarding partisan relationships, these results rose by 2% in the initial to 6% in the final test. On the other hand, another positive data is the decrease of the frequencies in the code of "others", in which we coded answers that did not make sense with what was demanded in the statement or this was blank. This code decreased by 44% in the initial test to 22% in the final. In conclusion, the frequencies of the final test, compared with the initial test, provide us with information to intuit that pupils begin to develop their understanding of geometrical figures.

### **Reasoning about the relationships among geometrical figures**

Initially, 12% of the answers were linked to the relationships among geometrical figures to the general set provided in the tasks. However, after the teaching experiment this percentage increased to 33%, where it was intended to develop the recognition of the critical attributes of the figures so that they could make relationships among geometrical figures. Of this total, regarding the hierarchical relations, the answer increased from 8% to 22%. Regarding to partitive relations, it increased from 2% to 6%. These data lead us to think that students begin to develop the relationships among geometrical figures.

## Discussion

The aim of this study is to know how students understand geometrical figures and how they reason about the relationships among them. We used a teaching experiment to check how geometrical thinking evolved if we introduced vocabulary and definitions related to hierarchical relationships. As well as, we analysed two tasks, from an initial and a final test, to verify this development of the understanding of geometrical figures. Data has shown us that many pupils answered the tasks perceptually without considering the relationships of the figures or the definition of the concept, in the initial test. In contrast, after the teaching experiment, in the final test, most of pupils began to identify attributes to the plane geometrical figures and to reason about the relationships among them. These data lead us to think that the development of the understanding of geometrical figures is progressive (Pegg & Davey, 1998; Satlow & Newcombe, 1998).

From these data, we have been able to begin to comprise the progress of the understanding of the plane geometrical figures in relation to Duval's theory (1995a, 1995b, 1999). Because students at the beginning did not know how to coordinate the apprehensions and after the teaching experiment, they began to coordinate the apprehensions making the necessary transformations, the relationships among attributes and the use of minimum attributes of the definition for doing the relationships among geometrical figures. In this way, while developing an understanding of geometric figures and how to relate them. They began to develop the personal figural concept (Fujita & Jones, 2007). Thus, we can intuit that the realization of the hierarchical classifications depends on the language that is used in the definitions of the geometrical concepts, which can help identify the minimum attributes to recognize a type of geometrical figure.

*In this paper we report about a small-scale classroom experiment on teaching area measurement with a digital geoboard. The two-lesson teaching sequence that was developed, was tested in two sixth-grade classes and was aimed at teaching students using measurement strategies in a flexible way. The pre- and posttest data were analysed both on task and student level. The results show that most of the students developed more flexible strategies, but many of them did not use them accurately. Our results indicate that apart from working on the ability of students to find correct answers, also the flexible use of strategies can be realized through education.*

*Keywords: Measurement, area, digital geoboard, strategies.*

## Introduction

Students often say that area “is length times width”. This suggest both that the conceptual understanding of area is lacking, and that they only have one strategy available for finding the area of figures, even if they have learned about finding area by counting units earlier: “It [...] is typical of many learning processes, especially in mathematics – that the original sources of insight have been clogged, and the way back to insight is blocked by the processes of algorithmising and automatising.” (Freudenthal, 1983, p. 209). In the new curriculum for Norwegian primary school, in-depth learning is important, and among other things the students are expected do “construct a robust and flexible understanding” (Ministry of Education and Research, 2015). Therefore, it is important to develop teaching that supports the learning of flexible strategies for area measurement.

## Theoretical framework and research question

Knowledge about measuring the area of polygons consists of both conceptual and procedural knowledge which are mutually supportive and should both be fostered (Rittle-Johnson, Schneider, & Star, 2015). Having a good understanding of measuring area means that students have several strategies available to determine the area of polygons. For example, they may count square units and/or half square units, make a multiplication to find the area of rectangles, decompose polygons into smaller, simpler polygons and use addition, may embed a polygon into a larger, simpler polygon and use subtraction, and may be able to apply a formula to calculate the area. Essential is that students can apply these strategies in a flexible way fitting to the problems at hand. However, there is evidence (Huang & Witz, 2011) that primary school students fail often in area measurement problems and have difficulties in flexibly handling area measurement problems. According to Huang and Witz (2011) this finding is considered to be linked to the emphasis that in teaching is put on formula memorization rather than on conceptual understanding and explaining your reasoning. Further, students who develop flexibility in problem solving use or adapt existing strategies to unfamiliar problems, and show a greater understanding of concepts (Star, Rittle-Johnson, Lynch, & Perova, 2009). Therefore,

it is important to investigate how students' flexible use of strategies in measuring area and their awareness of using them can be supported.

Most of the research on strategy flexibility or strategy adaptivity has been on mental calculation (e.g., Threlfall, 2009; Verschaffel, Luwel, Torbeyns, & Van Dooren, 2009) or on solving non-routine word problems (Elia, van den Heuvel-Panhuizen, & Kolovou, 2009). In the study of Verschaffel et al. (2009) a distinction is made between task, subject, and context adaptivity of strategies. In the present study we built on this research and explored how task flexibility of strategies for finding the area of polygons can be taught. We will not use the term "adaptivity" in this paper because although we will discuss appropriateness of strategies with the students, the main goal is to teach multiple strategies and discuss the relationship between them. Further, we will focus on inter-task flexibility in the tests (Elia et al., 2009), investigating whether students change their strategies from pre- to posttest.

One tool that is sometimes used for teaching measurement of area is the geoboard. However, there are only a limited number of empirical studies on this topic. For example, Bair and Cady (2014) observed that by means of a geoboard students could find Pick's theorem and the study of Britton and Stump (2001) showed that students could develop cut-and-paste strategies. To our knowledge, no research has been carried out to investigate whether the geoboard is suited to foster the development of flexible strategies. Therefore in this study our research question was: *Does working with the geoboard help students to use flexible strategies for measuring area?*

## Method

To answer the research question, a small-scale classroom experiment comprising a pre-post-retention-test research design was carried in two sixth-grade classes with 46 students during the period of February-July 2017. For this experiment we designed and tested a teaching sequence of two 75-minute lessons on reasoning about area measurement based on working with a digital geoboard.

The digital geoboard ("Geoboard [Computer software]," 2017) is an app for a tablet or computer that resembles the physical geoboard. Students can manipulate polygons and write computations or explanations on the digital geoboard, and they can share their work with the teacher through a sharing platform ("Showbie [Computer software]," 2018) or show it on a projector in the classroom. This makes it possible to select and present students' strategies to emphasize the connections between different strategies and give value to different strategies for the same task.

The lessons were taught by the researcher in the presence of the classroom teacher. In the lessons whole-class discussions led by the researcher were interchanged with students' individual work on the geoboard. In the discussions the use of different measurement strategies was stimulated, both strategies proposed by the students and strategies planned by the researcher, and students were made aware of the relationships between the different strategies. To support these relationships, the strategies were represented visually by drawings on the geoboard. To encourage students to think about their strategies it was emphasized that it is very important to be aware of the used strategy and that good understanding means that one can explain how the answer was found. This encouragement was given to the students both during their individual work and the whole-class discussions.

Type of task	Description	Task included in		
		Pretest	Posttest	Retention test
Blue task	Rectangle with sides parallel to the axes of the geoboard	Ü	Ü	Ü
Red task	Rectangle with sides $45^\circ$ to the axes of the geoboard	Ü	Ü	Ü
Brown task	Polygon in which partitioning into triangles and squares can be used	Ü	Ü	Ü

**Table 1: Overview of the tasks in the tests which are used in the paper**

The pre-, post-, and retention tests were administered in Week 5, 7 and 22 respectively. They contained several types of measurement tasks presented on paper-and-pencil test sheets. Table 1 shows which type of task is included in which test. In every test, for each type of task the to be measured area was varied a bit in order to avoid retest effect.

Figure 1 shows an example of how the tasks in the retention test were presented to the students. The question asked to the students was: «Can you find the area of the shape? Write how you were thinking. You may use the picture to explain.». The yellow square was given as an area unit. On a next page the students were asked to give a justification for their result. During the pretest it turned out that after giving this prompt it was for most students easy to *say* what their thinking was, but writing this down was harder for them. Therefore, the teacher and the researcher made clear to the student that they just had to write down what they said orally.

Den brune figuren har areal: \_\_\_\_\_

Vis hvordan du tenkte: \_\_\_\_\_

**Figure 1: Test sheet with the polygons and the questions the students have to answer**

The data from the test sheets were entered into NVivo. Both the students' measurement results and their explanations of the used strategies (see for examples Figure 2 and 3) were coded. When the

students found the correct area, the answer was coded as “1” and an incorrect answer was coded as “0”. Based on these codes we divided the students per task into four classes: the “00” students (incorrect answer in pretest and posttest), the “01” students (incorrect answer in pretest, correct answer in posttest), the “10” students (correct answer in pretest, incorrect answer in posttest), and the “11” students (correct answer in pretest and posttest). For coding the strategies, we used three main categories, namely “counting”, “multiplication”, and “restructuring” (decomposing or embedding strategies). Furthermore, we had two additional categories, namely “other” and “no strategy information available”.

## Results

Table 2 shows for each type of task and for each test the percentage of correct answers. For all the tasks which were both in the pre- and posttest, the students improved their performance of which the most gain was obtained for the Blue task. In the retention test this progress continued only for the Red and the Brown task.

Type of task	% correct		
	Pretest ( <i>n</i> = 43)	Posttest ( <i>n</i> = 41)	Retention test ( <i>n</i> = 43)
Blue task	70%	95%	88%
Red task	44%	51%	58%
Brown task	72%	80%	88%

**Table 2: Percentage of students who gave correct answers to the different types of tasks**

Even if the overall performance on each task was increasing, individual students showed both progress and deteriorating performance on each individual task. Using the red task as an example: Of the 36 students that participated on both the pre- and posttests, 11 students got the answer wrong on the pretest but right on the posttest, but 8 students got the answer right on the pretest but wrong on the posttest. Complete results are in table 3.

Type of task	Number of students belonging to a class of students			
	“00” student	“01” student	“10” student	“11” student
Blue task	0	8	2	26
Red task	8	11	8	9
Brown task	3	5	3	25

**Table 3: Number of students (*n* = 36) belonging to a particular class of students split out for the three types of tasks included in the pre- and posttest**

The next step in our analysis was figuring out what strategies the students used to find the area of the polygons and how flexible they were in using these strategies. We analyse the Red task as an example, because this is in our view the most interesting task that was on both the pre- and the posttest.

The strategies used in the Red task (see Table 4) were counting (in this case the number of squares and triangles), multiplication (length  $\times$  width; leading to mistakes because diagonal distances cannot be measured by counting), and restructuring. In the lessons it was made clear that this latter way of measuring the area for this task is very suitable, and we also showed why the multiplication strategy could not work easily.

Used strategy in the Red task in Pretest à Posttest	Number of students belonging to a class of students				Total
	“00” student	“01” student	“10” student	“11” student	
Counting à Counting	0	3	3	5	11
Counting à Restructuring	0	0	4	3	7
Multiplication à Counting	1	7	0	1	9
Multiplication à Restructuring	2	0	0	0	2
Multiplication à Multiplication	1	0	0	0	1
Other	2	1	1	0	4
No strategy in pre- and/or posttest	2	0	0	0	2

**Table 4: Students’ ( $n = 36$ ) strategies in the pre- and posttest applied in the Red task**

For this Red task, no student used the restructuring strategy before the lessons. Yet, after the lessons, nine students tried to apply this strategy, of which three got the correct answer. The work of one of these students is shown in Figure 2.

**Figure 2: Test sheets of students using restructuring as a strategy applied in the Red task in the posttest resulting in a correct answer, and in the Brown task in the pretest making an error**

The six students who got a wrong answer made various mistakes. Four of them give a clear explanation of the procedure of embedding the rectangle in a larger square and “subtracting what is in the corners which is not in the red [rectangle]”, but proceeded with computing the wrong area of the square (one student got  $7 \times 7$  as a result) or computed the wrong area that had to be subtracted (three students). Of the other two students the source of the error is unclear.

The fact that four “10” students go from correctly using a counting strategy to making mistakes with a restructuring strategy, is possibly related to the value we gave to this strategy in the plenary parts of the lessons.

Task type	Strategy	Number of students belonging to a class of students				Total
		“00” student	“01” student	“10” student	“11” student	
Blue	Same	0	6	1	18	25
	Different	0	2	1	5	8
Red	Same	1	3	3	5	12
	Different	3	7	4	4	18
Brown	Same	1	1	0	16	18
	Different	1	2	1	2	6
Total	Same	2	10	4	39	
	Different	4	11	6	11	

**Table 5: Number of students using the same or a different strategy in the pre- and posttest split out per task type**

Table 5 summarizes the findings of the correctness of the answers per type of task and whether there was a change in strategy between the pre- and posttest. In the Blue and the Brown task more students retained the same strategy than in the other tasks. Moreover, they even did not change the strategy when they got a wrong result in the pretest. In the Red task more changes happened. Here 60% of the students changed their strategy. We see in this table that many students use different strategies in the pre- and posttest, for instance 18 students changed strategies in the red task, but 7 (3+4) did not come up with the correct answer.

Student's strategy flexibility for the Blue, Red, and Brown task	Number of students ( <i>n</i> = 22)
Using only one strategy	3
Not changing strategy between pre- and posttest but changing it over tasks	2
Changing strategy between pre- and posttest in one task	11
Changed strategy between pre- and posttest in two tasks	6

**Table 6: Number of students who showed a particular strategy flexibility**

Taking again the perspective of the students, we could identify for 22 students their strategy flexibility in the pre- and posttest over the Blue, Red, and Brown task. As it is revealed by Table 6, a few students only used one strategy, but most students changed their strategy from the pretest to the posttest. Note,

that in this analysis the students which applied a strategy that could not be classified or was not available in the pre- and/or the posttest are not taken into account.

Student's inter-task flexibility	Pretest	Posttest
Using the same strategy on all tasks	7	5
Using two different strategies	15	14
Using three different strategies	0	3

**Table 7: Student's inter-task flexibility on the blue, red and brown tasks (N=22)**

We also analysed whether students used the same strategies or different kinds of strategies on the three tasks on the pretest, and the same question on the posttest, to investigate the inter-task flexibility of the students. We see that the inter-task flexibility of the students have increased on the posttest relatively to the pretest (table 7).

## Discussion

In this study, we investigated whether working with the geoboard could help students use flexible strategies for measuring area of polygons.

The problems on the pretest and posttest were routine in the sense that the polygons were shapes that the students could have worked with before. However, the problems were given on a grid and without rulers and calculators that the students might be use to have when measuring areas of rectangles. The students showed some inter-task strategy flexibility already at the pretest, choosing between multiplication and counting strategies. This is in contrast to the situation where students are given unfamiliar, complex problems, where the unfamiliarity and complexity of the problems may hinder the flexible change of strategies (Elia et al., 2009). However, the pretest also showed that some students chose inappropriate strategies, e.g. multiplication on tasks where this could not lead to a correct answer, even though they showed that they knew how to use a counting strategy that would have been appropriate.

Working with the geoboard, the students tried different strategies and shared with each other through whole-class discussion. They also tried the strategies that the researcher emphasized or introduced, e.g. counting or different rearranging strategies. The pre- and posttest results taken together (table 6 and 7) show that many students have developed their inter-task flexibility. Heinze et al. (Heinze, Marschick, & Lipowsky, 2009) raise the question whether the “investigative approach” that was used in the teaching, where students discuss and practice selected strategies, “prevent students from choosing strategies adaptively because they tend to ignore problem characteristics”. Because the posttest items are related to tasks which were discussed in the teaching, we can't address this question with certainty; however, the results show that many students on the posttest used more appropriate strategies e.g. on the Red task, even if they didn't use them accurately.

## Conclusion

Considering that this was only a small-scale classroom experiment with an intervention consisting of only two lessons, it was hard to draw conclusions. Nevertheless, although the students did not substantially improve their performance in measuring area, we can say that we have experienced that most of the students were active in thinking and trying out strategies for measuring area which were new to them, so working with the geoboard and discussing strategies in whole class helped many students develop their inter-task flexibility for measuring area. This made us more aware that apart from working on the ability of students to find correct answers, also the development of the flexible use of strategies is an important goal in mathematics education to work on.

In further work, we will do a controlled design experiment where the teaching period is longer, to be able to compare working with the geoboard with the ordinary curriculum, and to give the students the opportunity to develop more accuracy and strategy adaptivity.

*This paper reports research based on a K-6 prospective teacher education experiment carried out in a geometry course in the 2<sup>nd</sup> year of studies. The study aims to understand how participants justify generalizations about families of geometric figures in a context of exploratory teaching. Data were collected by audio and video records and from participants' written productions. In the analysis, special attention was given to the kind of arguments, their degree of generality, and the aspects that contribute for the learning of the justification process. The results show that initially the participants had difficulties in understanding how to justify generalizations. They progressed by using valid arguments, but they struggled in fully providing arguments and reasoning beyond specific cases. An improvement of justifications was achieved by the careful design of tasks, the interaction in the classroom and by relating the process of justification to understanding why a statement is true.*

*Keywords: Geometry, Reasoning, Justification, Generalization, Preservice Teachers Education.*

## Introduction

Lo and McCrory (2009) argue that prospective elementary teachers need to learn proof: a) as a tool to show or verify that something is true or false; b) as a mathematical object that is regulated by some rules and standards; and c) as a factor of students' development. These levels correspond to knowing how to proof, understand the nature of proof and to adapt proof to different students' developmental levels. However, Stylianides and Stylianides (2009) refer several studies showing that prospective elementary teachers have predominantly misconceptions about proof, particularly regarding the role of empirical arguments. Also Lin et al. (2012) add that, for many of these teachers, their belief in a result rests more on the authority of external entities than on their reasoning.

For Stylianides, Bieda and Morselli (2016), in the last decade, some research studies sought ways to support students in argumentation and proof, particularly in geometry. In teacher education, according to Lin et al. (2012), some studies suggest guidelines to improve the knowledge of prospective teachers in proof: solve tasks individually or in small groups; hold collective discussions; share and criticize one another's proofs; promote cognitive challenges. In geometry, the use of DGS and of suitable tasks may motivate the search for justifications to explain why conjectures are true (Christou, Mousoulides, Pittalis & Pitta-Pantazi, 2004). However, as Stylianides et al. (2016) suggest, in this area, there is still a need for research in designed interventions that focus on the development of prospective teachers' mathematical knowledge about proof. Assuming this, our paper addresses the need to support future teachers in the process of justification in geometry. Its purpose is to understand how they justify generalizations about families of geometric figures. We analyse the following questions: what kind

of arguments do participants use to justify generalizations about families of geometric figures? What are the obstacles and the facilitating aspects of learning to justify suggested by the experience?

## Mathematical reasoning and the process of justification

Lannin, Ellis e Elliot (2011) consider mathematical reasoning as an evolving process of conjecturing, generalizing, investigating *why*, justifying and refuting assertions. For these authors, generalizing is about identifying common elements or extending the reasoning beyond the range in which it originated. Investigating *why* involves investigating factors that may explain why a generalization is true or false. A valid justification constitutes a logical sequence of statements, each relying on established knowledge, in order to arrive at a conclusion; it must use general language demonstrating that it applies to more than one particular case, even if it is based on generic examples. In the context of teaching, a successful justification shows that a statement is true and explains *why* it is true.

Considering this characterization, we find the concepts of justification and proof to be very close, which results from the several meanings attributed to proof, both in research in mathematics education (Stylianides et al., 2016) and in mathematics, where there are many conflicting opinions about the role of proof and what makes a proof acceptable (Hanna, 2000; Harel & Sowder, 2007). Stylianides (2007) presents a definition based on the literature on the philosophy of mathematics and mathematics education that addresses mathematics teaching from the first years of schooling:

A proof is a mathematical argument, a connected sequence of assertions for or against a mathematical claim, with the following characteristics: 1. It uses statements accepted by the classroom community (set of accepted statements) that are true and available without further justification; 2. It employs forms of reasoning (modes of argumentation) that are valid and known to, or within the conceptual reach of, the classroom community; and 3. It is communicated with forms of expression (modes of argument representation) that are appropriate and known, or within the conceptual reach, of the classroom community. (p. 291)

Considering that we focus on justifying<sup>1</sup> generalizations concerning geometrical objects, the statements must relate to the geometrical structure of the objects. In this sense, we call on the ideas of Battista (2009), suggesting that reasoning involves spatial structuring—a special type of abstraction corresponding to the mental act of constructing an organization or form for an object or set of objects by identifying its components, combining them into spatial composites, and identifying the way they combine and relate—and geometric structuring (GS), which describes spatial structuring using formal concepts. Also, we should also consider Balacheff's (1988) “generic example” as a form of reasoning particularly suitable for justifying geometrical generalizations, as it “involves making explicit the reasons for the truth of an assertion by means of operations or transformations on an object that is not there by its own right, but as a characteristic representative of its class” (p. 219).

## Methodology

This paper addresses an investigation with an intervention, in order to change practices and enhance teachers' preparation in geometry. The research focus is on learning in context, starting from the

---

<sup>1</sup> From now on, instead of “proof”, we use the term “justification”.

conception of strategies and teaching tools, following a design-based research as methodology, in the form of a prospective teacher experiment (Cobb, Confrey, diSessa, Lehrer & Schauble, 2003) in which the teacher also plays the role of researcher. This approach is referred by Stylianides et al. (2016) as “a promising approach to respond to the need for developing effective ways to address students’ and teachers’ difficulties with argumentation and proof” (p. 344). Two of the design principles of the experience influence directly the tasks that we report in this paper: (i) make use of the intimate relation between sense making and the activity of reasoning and proving to promote learning with understanding; (ii) promote flexible reasoning, providing tools for prospective teachers, including different ways of justifying (Stylianides & Stylianides, 2006).

The data were collected during the second cycle of the study, involving a group of 25 trainees who attended a Geometry course (2<sup>nd</sup> year of the Basic Education Bachelor’s Degree). The tasks were solved in groups of 4/5 elements. Data gathered includes the participants’ records of two tasks solved in the classroom and audio and video recordings of the groups’ interaction.

We present a framework to analyse the justification of generalizations (Table 1) taking in account, first, the nature of the arguments regarding the geometric structuring of objects which relate mainly to the properties stated and, second, the degree of generalization of the justification.

Level	Argument’s nature	Properties / procedures	Degree of generalization
GS3	Based on the correct geometric structuring of the family of figures	States relevant and established properties	Uses a generic language about the family of figures
			It focuses on a generic example
			It focuses on one or more figures without generalizing
GS2	Based on the incomplete geometric structuring of the family of figures	States relevant and established properties, but omits others	Uses a generic language about the family of figures
			It focuses on a generic example
			It focuses on one or more figures without generalizing
GS1	Based on the incorrect geometric structuring of the family of figures	States irrelevant, non-existent or non-established properties	Uses a generic language about the family of figures
			It focuses on a generic example
			It focuses on one or more figures without generalizing
GS0	Without resorting to the geometric structuring of the family of figures	States numerical relations without connection to the structuring of the figures	It focuses on one or more figures
		Tests the generalization	It focuses on one or more figures
		Uses an external source of validation	Does not apply

**Table 1: Levels for justifications of generalizations about families of figures**

## Results and discussion

In this section, we discuss results from two tasks, one about the congruence of the vertically opposite angles and another about the sum of the amplitudes of the internal angles of a polygon. In a previous lesson, the participants used GeoGebra to conjecture about these relationships, but they were not supposed to use it in these tasks.

### Task A – Vertically opposite angles

Previously you discovered that two vertically opposite angles have the same amplitude. Find a justification explaining why this relationship is always true.

**Figure 1: Task for the justification of the congruence of vertically opposite angles**

This task was not the first asking for a justification involving angles, but it was the first one using a generalization in which no value was given, so the reaction of the participants was very different from the previous ones. There were only two written answers, one of them from Helena (Figure 2):

*As the vertically opposite angles have the same vertices (the straight lines always pass through the same point) any way we put the straight lines (any orientation), the angles were always equal.*

**Figure 2: Helena's justification for task A**

Helena's answer refers to a characteristic of vertically opposing angles, but her justification does not resort to geometric structuring because, by stating "any way we put the straight lines," she is drawing on her prior experience with GeoGebra. In this way, her justification implicitly refers to an external source to validate the claim, so the justification is incorrect (level GS0). Although based on empirical experience, the software represents the authority in which Helena trusts.

The other written answer is similar to most reactions, illustrated by the following dialogue:

- Marina: They have to be equal because they have the vertex in common and the sides of one angle are the sides of the other.
- Teacher: But what you are saying to me is almost the definition of vertically opposite angles. This statement does not justify the claim.
- Marina: So how do we justify it?

In an attempt to help the group, the teacher suggests introducing a value:

- Teacher: Imagine that  $a$  is equal to  $30^\circ$ . Try to find the values of the other angles without using the property.
- Marina: Which property?
- Teacher: The one that you want to justify. That vertically opposing angles are congruent. Find the other values from other relationships.

- Marina: Oh! So...  $c$  is 150... because adding  $a$  it gives 180 degrees. They are... supplementary.
- Teacher: OK...
- Marina: Then  $b$  is 30 because it is vertically opposite to  $a$ .
- Teacher: Attention! We agreed that we can not use this property. Do you understand why? You cannot justify that a property is true if you are using it in your reasoning.
- Marina: OK... Hum,  $b$  is 30 because it's supplementary to  $c$ , which is 150.
- Teacher: OK. As you can see you discovered the values 30 and 150 without using the property. Now, try to use a similar reasoning without using a specific value.

Marina shows some difficulties. On the one hand, she does not distinguish the characterization of the vertically opposing angles from the justification of their congruence. This problem may be due to the strong perception that angles have to be congruent by the way they are constructed. On the other hand, the simplified version of the problem using a specific value also shows that Marina does not know she cannot use the property she is seeking to. The group made an effort to continue the task, but they struggled to generalize the justification. Thus, this episode shows an answer based on an incomplete geometric structuring of the family of figures (EG2) which focused on a particular figure without generalizing.

### Task B – Sum of the amplitudes of the internal angles of a polygon

You have found a generalization for the sum of the internal angles of a polygon using GeoGebra. Let's try to justify it. To do this, look at the following hexagons. Each one suggests a possible strategy. Use one of the strategies to write the justification.

**Figure 3: Task for justification of the sum of internal angles of a polygon**

In the beginning, the prospective teachers struggled again with the absence of values because some thought that they would need the value of each angle, but the teacher then stressed that they should continue the strategies presented. This time, all the groups were able to produce some justification.

*The first hexagon is divided into 4 triangles. All vertices of each triangle cover all the internal angles of the polygon. If we know that the sum of the internal angles of a triangle is equal to  $180^\circ$ , we can multiply 180 by 4 (4 triangles) and we obtain the amplitude of the whole polygon. The expression that generalizes is  $(n-2) \times 180$ . If a polygon has 10 sides, it is possible to draw 8 triangles; if you have 6 sides, we draw 4 triangles. If we have  $n$  sides, we draw  $n-2$  triangles.*

**Figure 4: Celia's justification using the strategy of the first figure**

Celia's answer (Figure 4) is based on the correct geometric structuring because it identifies two relevant properties (the sum of the amplitudes of the internal angles of a triangle and the decomposition the polygon into  $n-2$  triangles). Celia uses the hexagon and the decagon with the intention to treat them like generic examples, because it explicitly indicates properties of the class. In this way, her justification is at level GS3<sup>2</sup>.

All groups used the strategy initiated in the first figure, but most of them decided to follow the other strategies as well. The next answer (Figure 5) belongs to Anita:

**Figure 5: Translated reproduction of Anita's justification**

Anita's justification is based on a correct geometric structuring, using relevant and established properties, although she does not explain the relation between the number of sides of the polygon and the number of triangles. In addition, the properties concern only the case of the hexagon, which is not used as a generic example, and are not explained properly, so the justification is incomplete and refers to level GS2. The restriction to the hexagon is a common problem addressed by the teacher:

- Teacher: But that's for the hexagon. What about other polygons? For example, a decagon?
- Isabel: We use... 8 triangles. We took two sides.
- Teacher: So?
- Isabel: Exactly. Then it gives  $(n-2) \times 180$ !
- Andreia: And for the other we do  $6 \times 180$  and then we take two triangles.  $2 \times 180$ .
- Teacher: And why do you take the angles of two triangles?
- Isabel: Yeah... This is you forcing to give the same result...
- Teacher: That's it. If you have to take something, some value, that has to make sense...

<sup>2</sup> We are only considering the quality of the arguments regardless of language errors.

In this dialogue, we observe that the participants are trying to extend the first strategy to the second case without understanding why. When the teacher confronts them, they recognise their problem.

## Conclusion

Task A showed trainees' difficulties related to two factors: the nature of the statement to be justified—a generalization—supported by a generic representation with no values; the principles of a justification, namely the impossibility of using a single example or relying on cyclic reasoning. The fact that the participants are able to solve a similar task by introducing a value shows that difficulties may not arise from the identification of relevant and established properties, but from the construction of an argument that applies this structuring to the entire family of figures. This means that the prospective teachers showed difficulties both in justifying and in understanding the nature of justification (Lo & McCrory, 2009).

The solutions of task B show a correct geometric structuring of the family of figures, using valid arguments, even if incomplete. Most justifications tend to be supported by specific examples, but in some cases, the participants try to present them as generic. The teacher suggests that the justifications shows why the relation is true and participants seem to accept that suggestion.

Thus, the two tasks show some differences with respect to the type of arguments used by the participants to justify generalizations, since they started to rely more on the correct structuring of the geometric figures. These differences may derive from the specificity of tasks, but may also correspond to a more correct conception of what a justification means. However, the solutions from task B show that there are two important aspects to attend. On the one hand, it is necessary to overcome the resistance in constructing an argumentative discourse, which we observe in justifications that are reduced to the schematic interpretation of expressions or visual representations, in order to value the communicative dimension of this process (Yackel & Hanna, 2003). On the other hand, it is important to raise the degree of generality of the discourse which, in some cases, is overly supported by particular examples and does not show that generalization applies to the whole domain of figures (Lannin et al., 2011). In fact, there is an unclear line between presenting a generic example that is representative of the domain (an acceptable strategy to justify) and supporting a justification by empirical examples, which corresponds to a common error and a misconception about the role of empirical results in the validity of a justification (Stylianides & Stylianides, 2009).

The results presented refer only to two tasks used to promote the ability to justify generalizations. However, they confirm the relevance of relating the process of justification to understanding why a statement is true, suggested by several authors (e.g., Harold & Sowder, 2007; Lannin et al., 2011; Stylianides et al., 2016). In particular, the design of tasks that promote the construction and confrontation of different justifications and representations, as well as an environment of peer interaction, seem to be contributing factors in the development of the ability to justify.

## Acknowledgment

This paper reports a research developed within the scope of the project Geometric reasoning and visualization in a K-6 prospective teacher education program supported by the Centro Interdisciplinar de Estudos Educacionais – reference ESEXL / IPL-CIED / 2016 / A12.

# Professional actions of novice teachers in the context of teaching and learning geometry

Caroline Bulf

University of Bordeaux, Lab-E3D EA 7441, France ; [caroline.bulf@u-bordeaux.fr](mailto:caroline.bulf@u-bordeaux.fr)

*This paper aims to describe the professional actions of beginning teachers in the context of teaching and learning geometry. Using different theoretical tools, our research is based on the observation of lessons (with students aged between 6 and 11) delivered by beginning teachers in France. The paper seeks to show how the specific context of geometry impacts on professional actions especially among beginning teachers.*

*Keywords: Geometry education, teacher professional actions, beginning teachers.*

The first part of the article describes the theoretical background and research questions. The second part is dedicated to the methodology and results from several observations of novice teachers in the context of teaching geometry. The final part of the article is an opportunity to discuss with new perspectives in the context of pre and in-service teacher training.

## Theoretical framework in terms of *teacher professional actions*

This research takes part of a bigger collaborative research which deals with different fields (mathematics, literature, sciences...); the goal is to study conditions of development of teacher professional actions through the follow-up of a cohort of dozen of beginning teachers. In order to compare analyses we need a common theoretical framework, we describe it in next part.

Jorro (2002) distinguishes *generic teaching actions* from *professional actions*<sup>1</sup>. The former are attached to a collective culture shared by a community such as stereotyped actions (*writing on the blackboard, calling a student up to the black-board, putting a finger to the lips meaning quiet, etc.*) while the latter are more a singular and contextual conception. We refer mainly to Bucheton and Soulé (2009) to define more precisely *teacher professional actions*. These authors define professional actions as teacher's acts (physical or verbal) and the permanent "adjustments" in relation to student activity and knowledge at stake. These authors describe their organization and dynamics through the "multi-agenda of entrenched concerns [our traduction]" (*Ibid.*, p.32; schema 1 for an adapted version). The five concerns are:

- *leading the lesson* (organization and coherence of the lesson, through its material, spatial and functional dimensions);
- *atmosphere* (maintaining dialogical spaces);
- *linking* (making connections with what pupils already know or connections between other knowledges);

---

<sup>1</sup> Our traduction from Jorro's original notions of « geste du métier » and « geste professionnel ».

- *scaffolding* according to Bruner’s meaning i.e. helping pupils do and say things without doing it for them (Bruner, 1983);
- the targeted *knowledge* (central component).

For us, professional actions are specific, situated, on a given context and moment, and led through didactical intention(s) (that means these “intentions” are more or less with direct and conscious links with the teaching project). It is important to notice now this theoretical framework’s goal is not about to give a binary classification generic/specific we recuse. What seems rightly interesting in the use of this general theoretical framework is that it can be mobilized in order to analyze any classroom session. Therefore, this is interesting in the cross of didactical analysis from different fields, which is the goal of the bigger research in which our collection of data fits. This paper deals with professional actions of beginning teachers in the context of teaching geometry.

### **Focus on beginners**

In this framework, the dynamical organization of professional actions determines teachers’ “postures of scaffolding<sup>2</sup>” some of which can be exaggerated among beginning teachers. The “posture of control”, for example, is frequently observed because they try above all to organize their work in relation to time and space, without taking into account the students’ potential activity. “Linking is rare. Pupils are usually addressed collectively and the atmosphere is relatively tense [our traduction]” (Bucheton & Soulé, 2009, p. 40). Furthermore, Robert and Rogalski (in Vandebrouck, 2013) define teacher’s practices as complex, stable and coherent. According to these considerations, it is therefore relevant to study the practices of teacher since their beginning to better understand the conditions of genesis and development of professional teacher actions. Especially since the generic teaching actions have been identified as being the ones that beginning teachers will try to incorporate into their practices (Jorro, 2002). How do the teacher actions become professional and relevant? What impact do the specificities of teaching geometry have on the implementation and articulation of these actions? What impact on potential students’ learning?

### **The specific context of teaching and learning geometry**

A lot of works relate the difficulties of teaching and learning geometry. Indeed, geometry is unique and complex in terms of the role of material activity (using instrument, manipulation, modeling...), visualization and language for the construction of mathematical concepts, as described in previous CERME (Jones & Al., 2017). We assume in our work there are mutual influences (and not subordinated one to another) between visualization (according to Duval’s meaning, 2005), instrumental action (graphical register) and language (Bulf, Mathé & Miltalal, 2011). In doing so we seek to describe teacher’s actions more precisely in our analysis, taking into account the different manifestations of geometrical concept (graphical register, verbal formulation, coding, physical gesture, etc.). According to Duval’s framework (2005), we refer to the “dimensional deconstruction” to analyze geometrical object at stake in terms of figural units (2D for surface, 1D for line and 0D for point as intersection of lines), and relations between these different units. In

---

<sup>2</sup> “Accompaniment, control, letting go, teaching-conceptualization, magician” (Bucheton & soulé, 2009, p. 41)

other words, this is our additional and specific theoretical background to take into account the context of teaching and learning geometry.

The goal of this paper is to highlight the fact that professional actions are formed early (as mentioned at the beginning of this paper) but, depending on the task assigned to students in the context of teaching geometry, that they may hinder understanding of the geometrical concepts under consideration. We try to describe the reasons of these misunderstanding because, precisely, same professional actions could be, on the contrary, relevant in other context of teaching. That's why our theoretical framework seems particularly interesting because it contributes to show clearly the limits of dichotomy genericity / specificity of professional actions in pre and in-service teachers training. We summarize our theoretical framework in the schema 1. The central component (from Bucheton and Soulé' framework) is here the geometrical *knowledge* at stake, and therefore according to our theoretical framework, it is observed in activity through three dimensions: visual, oral and instrumental.

**Schema 1. “multi-agenda of entrenched concerns” (Bucheton and soulé, 2009, p.33) adapted to the context of teaching geometry.**

The specific context of geometry teaching with beginning teachers allow us to highlight obstacles or potential levers to better understanding professional development of teacher. This paper tries to answer to the research questions : How do the specificities of teaching geometry (in terms of visualization, instrumental action and language) have an impact on the implementation and articulation of professional actions (schema 1) ? What impact on potential students' learning?

## Methodology and results

Our corpus is composed of several videos and transcripts of lessons, visit reports, professional writings, interviews, etc. collected during pre-service teachers and during the first years of practice of a dozen of beginning teachers since 2013. In the present contribution we chose to refer to the professional actions of three teachers, Maya, Emilie and Celine observed in 2016 and 2017. We

think these case studies are representative of novice teachers' practices in the context of teaching and learning geometry<sup>3</sup>.

Our analysis methodology is qualitative and based on classical models in the French field of didactics of mathematics, known as *a priori* or *a posteriori* analysis according to the Theory of didactical situations in mathematics (Brousseau, 1997). A *a priori* analysis is an epistemological reasoning which does not have a predictive sense, but instead a causal one; it involves describing various possible (and therefore potentially reproducible) phenomena in teaching session. Our *a posteriori* analysis places contingent facts in the context created by the *a priori* analysis. Furthermore, our data are analyzed in accordance with our theoretical framework, which means we describe geometrical activity (*a priori* and *a posteriori*) through its different manifestations: visual, instrumental or verbal (as already described in previous paragraph). We infer from these analyzes hypotheses in terms of professional actions as we have described in our general theoretical framework (schema 1). We pay attention on the different type of teacher's scaffolding, leading, linking and atmosphere own to these teachers in relation with the geometrical knowledge at stake.

### **Over-scaffolding through different dimensions (verbal / visual / instrumental) of geometrical activity**

This episode is frequently encountered in classes ; it's about talking collectively about a figure on the blackboard. We refer here to a observation occurred in 2017 in Celine's class (with students aged 8 to 9). Students have to reproduce the figure given on the left extremity of the figures 1.

**Figures 1. Different ways of seeing one side of the square**

The different ways of seeing one side of the square as also the diameter of the half-circle<sup>4</sup> is the key to solve this problem. It is necessary to go beyond a first vision as a simple border line between two juxtaposed figures:

- this side is perpendicular to 2 other sides (relationship between 2 objects of dimension 1D);
- this side is a segment, which is also a diameter of the half-circle. The middle of this segment is the center of the circle (different objects 1D and 0D, and their relationships).

These different ways of seeing this “simple” figure are not self-evident because it involves different figural units (lines, points) and different kind of relationships (belonging, middle, perpendicular,

<sup>3</sup> Given what we have observed and analyzed so far in our previous researches and in the corpus for this research (corpus made up of a dozen novice teachers).

<sup>4</sup> « double designation » (Duval, 2014, p.5) of a figural unit.

equal distance...). If we focus on the center of the circle, there is *a priori* a lot of different ways to understand it (without being exhaustive):

- a point belonging to the side of the square (which requires to see a line as a set of – infinite – points, but it is far from being acquired for students of this age);
- the middle of a segment of which the ends are the vertices of the square: here coexist two ways to see points (vertex / end of segment);
- the center of the circle is where we will put one branch of compass ;
- the center is the point located to equidistant from the line (or points) defining the half-circle;
- the center is the junction point of the union of two rays in the same direction (here);
- ....

At the beginning of the session, Celine tries to explain the task by making the students talk about the instrumented actions. It is kind of over-scaffolding without linking the different possible ways of seeing the side of the square and the center of the circle:

Celine: How do I put my compass on my square?

Student: on the board there is a line in the middle to put the starting mine in the middle of the line

Celine: then in the middle of the line you speak about side [She sweeps the side with a hand gesture and points the middle of the side, figure 2] okay what is it in relation with our circle /// you remember where he is the center of the circle? // How is it called? [Sweeps the side of a hand gesture like the moment before from top to bottom] /// all of this / yes it is the diameter / there [gap between the auriculaire and the thumb, figure 3] it is the radius / you remember the center of circle [pointing finger, figure 2] it is the middle of the diameter/ it shares the diameter in 2 radius.

**Figure 2. physical gesture of pointing finger**

**Figure 3. physical gesture of finger spacing**

In less than two minutes, there are 9 different oral designations (*square, side, line, diameter, radius, middle of the line, center of the circle, middle of the diameter, this-there*) and 3 different physical actions that all rely on the same graphical sign on the blackboard. The same sweeping movement of the hand sometimes refers to the diameter of the circle or the side of the square or the radius (if the amplitude is shorter). The pointing finger indicates at the same time where to put the branch of the compass, the center of the circle, the middle of the diameter, the middle of the side of the square, the junction between two rays. This kind of scaffolding, both verbal and physical, characterizes the

teacher's will to help student through multiple designations, reformulations,... and as the beginners think they should provide. But this exemple is, in our opinion, representative of potential misunderstandings on the construction of meaning through these teaching actions. Indeed, different ways of thinking of the same objects are consciously mobilized, but it is as if going from one vision to another is self-evident, without linking: we move from the designation of objects to their relationships and their operationalization through instruments. At this student's age all these connections are not yet built. Here we are one of classical teacher interventions in geometry teaching, not especially with novice... The big question is : how to manage the complex specificity of geometrical activity : *the way of seeing a figure, the way of acting* with geometrical tools or not, *the way of speaking* ? We refer here to researches already exposed in previous CERME (Bulf, Mathé, Mithalal, 2011) (Barrier, Hache, Mathé, 2013) ; they proposed different theoretical tools to analyse geometrical activity in this way.

### **Different impacts on students' learning from scaffolding on the necessary and sufficient conditions for building a square**

Two novice teachers, Maya and Emilie, in 2016 prepared together a lesson (for students aged 8 to 9 years old). The students have to reproduce a square of 10 cm of side. At the end of the collective phase, both teachers chose to proceed by "dictation to the adult" that means students gives oral instructions and the teacher executes them to build the figure. An interesting moment happens when three sides of 10 cm and 2 right angles are correctly drawn at blackboard with expected geomerical tools. Both teachers ask to students « do we need set square to close the square ? » which is, in both cases, a spontaneous move. The question is : is it a relevant professional action ?

In Maya's class, she retains the one who talk about the set square to finish the construction. But Maya asks to students about the validity of another student's proposal who suggests to draw the line directly without the set square. This student, Nicolas, is also a student usually in difficulty.

Maya: Would Nicolas's technique have worked? Nicolas can you explain why it would have worked? [...] So you tell me we did not need the set square to draw the last line we could do directly with the rule to draw the last line.

The students do not validate Nicolas's technic because precisely it does not use the set square. On one hand they may reply this because it corresponds to what is worked precisely in this lesson, this is the didactical contract (Brousseau, 1997) and on the other hand probably because Nicolas is a student usually in difficulty... But here teacher's question is about the necessary and sufficient conditions for building a square, which is out of didactical contract for these students at this age. The teacher is stuck because Nicolas is right, it is mathematically correct. Therefore Maya chose to validate it and she concludes with theoretical argument: « As long as I have 3 sides of the same length and 2 right angles », which is, actually out of contract but in the same time it is also an opportunity to value this student (*atmosphere concern*).

Maya: Nicolas' proposal it would have worked / I connected well / I took my rule and my set square to do it but if I had connected this first line that I had done with it, it would have made me too the 2 right angles in the case ok where I already had the 2 right angles and the 3 sides which made the same length. Alright ... With my set

square I did the same thing as Nicolas proposes, I connected the 2 parts of the line, I did it with the square but we could do it directly with the rule .

Whereas in Emilie's class, Emilie also relies on a student's proposal but the student stands on a graphical argument that Emilie resumes directly : « yes you have already drawn both lines you need to connect » « I just have to connect ». We stay in a primary school contract strongly linked to graphical register.

## **Conclusion, discussion and perspectives about pre and in-service teacher training**

From the previous paragraph, we pointed out the necessary and sufficient conditions (here to recognize a square) are usually not anticipated by novice teachers and this may have a direct impact on teacher's scaffolding and therefore on student's learning. In one case, students may be confused at the end of the session on the contract at stake about the use of set square whereas in the other case, we stay in a contract in a paradigm of Geometry I (Kuzniak, 2018) that means validation is done within a graphical register.

This paper is also based on other case studies. We described at the beginning of the paper how Celine was overwhelmed by the managing of different dimensions own to geometrical activity (way of speaking, way of seeing and way of acting -with geometrical tools or not) about graphical figure. This is a typical novice's teacher action : novice teachers want to help students (when they give instructions at the beginning of the lesson) with multiple designations, reformulations,... but in the geometrical context, this may involve over-scaffolding through all registers in the same time (graphical, visual, discursive) and brings more confusion than help.

In previous work (Bulf 2016), we described how novice teachers try to play school teacher through the embodiment of « caricatural » teaching actions with an over-leading about rigor on semiotic representation of geometrical objects (vocabulary, coding, or quality of drawing<sup>5</sup>).

We believe these teacher's actions with novice teachers are actually not reserved for novices... That's why our research gives perspectives for pre-service and in-service teacher training to better understand the conditions of professional development in geometry teaching but not only. Our research in progress crosses results with other fields. We think this kind of research gives the opportunity to discuss the limit about a theoretical framework based on genericity of teaching actions. Indeed, in our different examples we may recognize teachers' actions shared by teacher community (*have students talk about the validity and rigor of their production; to explain in different ways the same thing ; to compare opinions between students etc.*) but it seems important to highlight the fact that these actions may be rich in potential misunderstandings in the context of teaching geometry. Even more, our study, in the context of teaching and learning geometry, suggests that it makes no sense to consider teacher's actions from a generic point of view because

---

<sup>5</sup> This is quite typical for beginning teacher in France. We suppose that may come from the fact the competitive exam that these young teachers had to pass requires a theoretical and deductive hypothetico reasoning of the Euclidean geometry.

each teaching actions are always specific and connected to a specific knowledge which requires its own and specific actions. This opens the more theoretical discussion of theoretical frameworks that seek to model teaching activities.

# A model of the instrumentation process in dynamic geometry

Madona Chartouny<sup>1</sup>, Iman Osta<sup>2</sup> and Nawal Abou Raad<sup>3</sup>

<sup>1</sup>Lebanese University, Lebanon; <sup>2</sup>Lebanese American University, Lebanon; <sup>3</sup>Lebanese University, Lebanon [nabouraad@ul.edu.lb](mailto:nabouraad@ul.edu.lb)

*Abstract. The present study investigates students' instrumentation processes while solving open geometry problems in a dynamic geometry environment. It aims at developing an analytical and comprehensive model of students' conceptual schemes and strategies built around the use of the tools available in DGE. The study was conducted in a grade-10 math class in a Lebanese school. Data were collected through whole-class observation with analysis of paper-based data and closer observation of 12 pairs of students. The analysis focused on the instrumentation process that occurred during the construction and manipulation of geometric figures. The results suggest the development of a three-phase model of the instrumentation process.*

*Keywords: Instrumental genesis, instrumentation process, dynamic geometry, grade 10.*

## Introduction

For the past few decades, research has investigated students' interactions with digital curriculum materials, analyzing the nature of tasks employed and the ways students act and react in such environments. The Instrumental Approach, elaborated by Verillon and Rabardel (1995) provides an adequate context to analyze such interactions. They made an important distinction between an artifact and an instrument. An instrument does not exist by itself. An artefact, which is the physical object, becomes an instrument when the user appropriates pre-existing schemes, or constructs personal schemes and integrates the artifact within his/her activity. Beguin and Rabardel (2000) and Trouche (2004) defined the concept of instrumental genesis to encompass two dimensions that contribute to the construction and advancement of an instrument: (1) instrumentation: it is subject-oriented and it entails the artifact printing its mark on the subject, i.e. it allows him/her to construct and enhance operative utilization schemes. (2) Instrumentalization, which concerns the development of the artifact component of the instrument.

Many researchers (Alqahtani & Powell, 2016; Artigue & Mariotti, 2014; Baccaglini-Frank & Mariotti, 2010) have used the Instrumental Approach to analyze the use of DGE tools in learning situations. According to Artigue and Mariotti (2014, pp.338) "representations play a fundamental role in the "generation" of mathematical meanings, and this role is assumed to be crucial in the teaching/learning of mathematics. Digital artifacts can provide representations of mathematical objects with a clear potential of generating mathematical meanings." These shared theories concerning artifacts and mathematical representations highlight the essential role that digital tools play in learning mathematics and hence the importance of understanding the way students instrument these tools in a DGE to create geometrical meanings. Alqahtani and Powell (2016) and Baccaglini-Frank and Mariotti (2010) studied the instrumentation process of the dragging tool. The analysis showed that the appropriation and application of the dragging tool started with random dragging and then looking at the characteristics of the objects being dragged in order to understand properties of dynamic constructions. The retroactions of the DGE that occurred while dragging different objects helped in identifying and understanding geometrical relationships such as invariants and

dependencies in the figure. While appropriating the use of the dragging tool, the construction of the dynamic figures came last.

Given that in the literature the primary focus in the process of instrumental genesis has been on the role of DGE tools and their impact on students' learning, this study, focuses on the instrumentation process, and aims at developing an analytical and comprehensive model of students' conceptual schemes and strategies built around the use of the tools available in DGE by answering the following question: "How do grade 10 students develop and structure their conceptual schemes and strategies while constructing a geometric figure using DGE tools?" The study consisted of a series of observations of 12 pairs of 10 graders (15-17 years old) who worked on open geometrical proof problems within Geogebra. Data were collected using video-recording and collection of materials, namely any paper trace (sketches, scribbles, conjecture or proof formulations) generated by students, together with their GeoGebra files. This paper presents students' work on two problems previously used by Olivero (2002) and Arzarello et. al. (2002):

*Problem 1 (Olivero, 2002)*

Let ABCD be a quadrilateral. Consider the bisectors of its internal angles and the intersection points H, K, L, and M of pairs of consecutive angle bisectors.

- 1) Drag ABCD, considering different configurations, and explore how HKLM changes in relation to ABCD.
- 2) Write down conjectures and prove them.

*Problem 2 (Arzarello et. al., 2002)*

Given a triangle ABC, consider P the midpoint of [AB] and the two triangles APC and PCB.

- 1) Explore the properties of the triangle ABC which are necessary so that both APC and PCB are isosceles (in this case, the triangle ABC is called "separable").
- 2) Write down conjectures and prove them.

The chosen problems: 1) are in accordance with the definitions of open problems; 2) are problems whose nature is not changed by the DGE, which simply acts as a visual amplifier facilitating the mathematical task; 3) lie in a mathematical conceptual domain familiar to the students, their difficulty does not reside in the understanding of the wording and meaning of the given of the problem; 4) were selected from other studies that analyzed students' work in a DGE.

## **Analysis of the Instrumentation Process**

The observations and analyses showed that, through their interaction with the tool, students gained new geometrical knowledge indigenous to the DGE. These gains were built in a continuous process of exerting intentional actions, processing feedback and adapting techniques. When students employed a certain tool among those offered by the DGE for the first time, or when they employed a tool known to them in a novel context, they processed the feedback it provided and adapted their techniques accordingly. The analysis of the 12 cases helped us identify three phases through which instrumentation and resulting geometric knowledge indigenous to DGE were developed. We illustrate

these three phases using the following examples, chosen among the 12 cases as they are the most representative examples:

### Example 1

While working on problem 1, a pair of students started their work by constructing two segments  $[AB]$  and  $[AD]$  and selected the *Parallel Line* tool to complete the parallelogram ABCD.

Phase 1: The students clicked on D, the point through which the parallel line to  $(AB)$  should be constructed, and waited, expecting the parallel line to appear. They were not aware of the fact that the construction needed another input, i.e. the line that determines the direction of the parallel line.

It is observed that the students were not familiar with the type and nature of inputs required by the *Parallel Line* tool. Their choice of input, namely point D, was purely experimental, based on the way they would construct a parallel line through D in the paper-and-pencil environment, i.e. placing the ruler to pass through D in a parallel direction to  $(AB)$ , without explicitly invoking  $(AB)$ .

Phase 2: They refined their input by incorporating the line to which the parallel line should be constructed but they started by clicking on  $(AB)$ , thus the line appeared confounded with  $[AB]$ . They still needed to select the point through which the parallel line should pass. They dragged the line and adjusted it visually till it passed by D and constructed a point C, through which the parallel line passes, by placing it as the fourth vertex of the parallelogram ABCD based on perceptual approximation (Figure 1). Although the parallel line appeared to be constructed in the correct position, but the figure did not hold under dragging since it was based on visual approximation. Therefore, they proceeded by constructing a parallel line to  $[AB]$  through D, a parallel line to  $[AD]$  through B and constructed C as the intersection point of these two lines (Figure 2). In this phase, the students adapted their use of the *Parallel Line* tool to the feedback provided by the tool itself. This adaptation was based on progressively gained knowledge and understanding of the nature of the input requirements for the parallel line to be constructed, rather than on speculations as they did previously.

Phase 3: By the end of the process, the students learned the two defining elements that determine a line parallel to another through a point. They understood the technical functioning of the *Parallel Line* tool. They succeeded in internalizing the utilization scheme of the *Parallel Line* tool since the input was refined based on understanding; their new knowledge was validated for them by the fact that the figure held under dragging.

**Figure 1: Adapting the use of the *Parallel Line* tool based on the tool's feedback**

**Figure 2: Using the *Parallel Line* tool based on conceptual understanding**

## Example 2

In problem 2, based on a paper sketch, a student hypothesized that  $ABC$  is separable when it is right isosceles. They decided to test her hypothesis in DGE.

Phase 1: They constructed a right isosceles triangle  $ABC$  by taking  $C$  as the intersection point of the perpendicular bisector of  $[AB]$  and the circle centered at  $P$ , the midpoint of  $[AB]$ , with radius  $[PB]$  (Figure 3). They selected the dragging tool and attempted to drag  $C$  on the circle. We note that the choice of the right isosceles condition and the attempt to drag  $C$  on the circle were both experimental processes that needed to be refined.

Phase 2: When  $C$  could not be dragged on the circle, the students discussed and analyzed what they observed and deduced that, since  $C$  is an intersection point, it could not be dragged on the circle. This novel understanding led them to adapting their construction by considering  $C$  as a point on the circle, without belonging to the perpendicular bisector of  $[AB]$  as well (Figure 4). They dragged  $C$  on the circle and observed that  $ABC$  is separable when it is a right triangle.

Phase 3: The students were able to develop novel understanding based on the interaction with the dragging tool:

- They understood that intersection points could not be dragged as they are dependent on other objects. This concept is indigenous to the DGE since in the paper-and-pencil environment students are not trained to distinguish dependent from independent points.
- The students were also able to understand that  $ABC$  right triangle at  $C$  is a sufficient condition for the triangle to be separable; it does not need to be isosceles as well.

**Figure 3: Constructing C based on experimental choices**

**Figure 4: Refining the construction of C based on conceptual understanding**

## Example 3

A pair of students who worked on problem 2, attempted to measure  $\widehat{ABC}$  using the *Angle* tool.

Phase 1: They selected only the vertex of the angle, which does not produce the desired result and keeps the DGE waiting for more input. Then, they selected the three points of the angle but in random order, which, in this case, resulted in displaying the measure of the outer angle.

Phase 2: To solve this problem and find the measure of the inner angle the students read the measure of the outer angle and subtracted it from  $360^\circ$  to find the measure of the inner angle. Here, the students

did not rely totally on the tool, neither did they try to adapt their use of the tool. Instead they solved the problem at hand using a previously acquired geometrical property. They did not attempt to understand the behavior of the *Angle* tool and to adapt their work accordingly.

Phase 3: The students were not able to develop conceptual knowledge indigenous to DGE; although prior geometrical knowledge was used to reach the result that the DGE failed in providing, that knowledge was not novel and was not indigenous to the DGE neither was it invested to build a new knowledge indigenous to the DGE.

### **The three-phase model of the instrumentation process**

From these examples we can identify a common structure for the instrumentation process of DGE tools. Each exploration in each example went through three phases: a phase of *heuristic application* of the tool, followed by a phase of *contextualized adaptation* leading to the third phase of *conceptual understanding*. These phases suggest the development of a three-phase model of the instrumentation process defined as follows:

Phase 1– *Heuristic Application*: The students choose a certain tool, and then select the object(s) they believe to fit the required nature and order of input. The choice of input is experimental based on students' experiences in a paper-and-pencil environment and on assumptions and speculations rather than formal knowledge.

Phase 2 – *Contextualized Adaptation*: After *heuristic application* of the tool, students build on the feedback it provides to adapt their strategies to the situation at hand. This adaptation can be based either on geometrical understanding (i.e. epistemic adaptation) or on practical considerations (i.e. pragmatic adaptation).

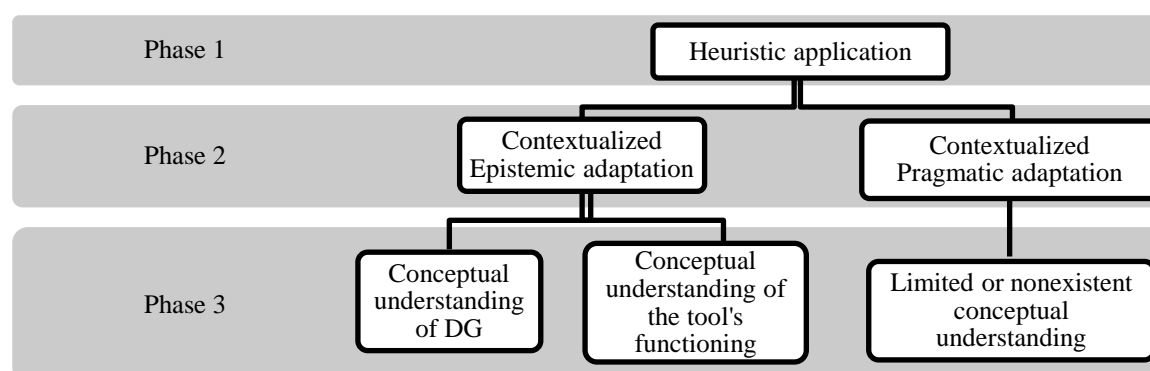

- Epistemic adaptation: Heuristic application of the tool evolves into epistemic adaptation as students benefit from the feedback provided by the tool to improve their strategies and construct new meanings. The utilization scheme of the tool is formalized by the mediation of the heuristic experiments carried out in the first phase.
- Pragmatic adaptation: Students manage to accomplish the given task but in a way that is based on practical considerations; the heuristic experiences do not evolve into mathematically grounded application of the tool. In this case, the construction of geometrical knowledge indigenous to the DGE, i.e. phase 3, is limited or even non-existent.

Phase 3 – *Conceptual Understanding*: The epistemic adaptation generates new understanding imprinted on the student by the tool. This understanding is not totally gained in phase 3; instead it is gradually constructed as of the first phase. The conceptual understanding is relevant to:

- The functioning of the tool: Students construct an understanding of the behavior of the tool, i.e. the type of input required, the context in which the input applies and the outcome that the tool provides.
- Dynamic geometry i.e. geometrical knowledge indigenous to the DGE: Students construct first-hand understanding of the geometry underlying the tool, which may be, in some cases, fundamentally different from the geometry learned in the paper-and-pencil environment.

Through these three phases, students gradually conceptualize a new type of geometry, the dynamic geometry.

The following diagram (Figure 5) illustrates the three-phase model of the instrumentation process.

**Figure 5: The three-phase model of the instrumentation process**

## Discussion and Conclusion

According to Beguin and Rabardel (2000), the instrumentation process, which is learner-oriented, entails the artifact printing its mark on the learner; it thus leads to the construction and development of utilization schemes. Therefore the three-phase model of the instrumentation process can be perceived as a more formalized utilization scheme for DGE tools. Beguin and Rabardel define these utilization schemes as contingent upon the meanings attributed by the individual to a situation; this subjective involvement of the students, while using technology, explains why technology does not have the same power and potential for all students. In fact, in phase 2 of the structure, the contextualized adaptation is contingent upon the meaning that students give to the situation; this is why some students are able to develop a *contextualized epistemic adaptation* and exploit the potentialities of the technological environment, whereas others can only develop a *contextualized pragmatic adaptation* limiting the potential of the DGE. Beguin and Rabardel add that utilization schemes are active structures as they are adapted to an expanding range of situations and their construction necessitates the intelligent use of both conceptual and technical knowledge. This idea is illustrated in phase 3 of the structure presented above, where students adapt their use of the tool to different situations and gain conceptual and technical knowledge of dynamic geometry.

We now compare this structure to a model developed by Leung (2011, 2017). The purpose of this techno-pedagogic task design model is to serve as a heuristic to design mathematical teaching and learning tasks in a technological environment. It is useful to compare these two structures in order to verify whether the way a task should be designed in DGE (i.e. according to Leung's model) is in fact consistent with the way students solve a task in DGE (i.e. according to the common structure of instrumentation processes developed in this study). These two structures are compared and contrasted in Table 0.1.

Table

0.1

*A comparative summary of the common structure of instrumentation processes identified in the current study and the techno-pedagogic task design model*

	<b>The common structure of instrumentation processes (identified in this study)</b>	<b>The techno-pedagogic task design model (Leung, 2011, 2017)</b>
Phase 1	<i>Step 1 – Heuristic application:</i> The choice of input for a specific tool is based on students' personal understanding of what is required to define a geometric object and of what is necessary in terms of the nature and order of input.	<i>Establishing Practices Mode (PM)</i> PM1 Construct and manipulate mathematical objects using tools embedded in a technology-rich environment PM2 Interact with the tools in a technology-rich environment to develop (a) skill-based routines; (b) modalities of behavior; (c) modes of situated dialogue.
Phase 2	<i>Step 2 – Contextualized adaptation:</i> Epistemic adaptation or pragmatic adaptation.	<i>Critical Discernment Mode (CDM)</i> Observe, record, re-present (re-construct) patterns of variation and invariant.
Phase 3	<i>Step 3 – Conceptual understanding:</i> The <i>epistemic adaptation</i> generates new understanding of geometrical concepts indigenous to the DGE and/or of the technical functioning of the tool.	<i>Establishing Situated Discourses Mode (SDM)</i> SD1 Develop inductive reasoning leading to making a generalized conjecture. SD2 Develop discourses and modes of reasoning to explain or prove.

In phase 1 of both structures, students practice the use of the tool and develop modes of interaction between them and the tool. Thus the process of instrumentation begins where the student acts on the tool and the tool shapes the student's knowledge thus creating an artefactual and psychological instrument.

In phase 2 of both structures, namely *contextualized epistemic adaptation* and *CDM*, the process of instrumentation continues; the students shift their attention from establishing routine usage of the tool to constructing mathematical meaning. A process of internalization takes place where technical tools are transformed into psychological tools for the purpose of shaping new meanings. However, the common structure of instrumentation processes includes a step, namely *pragmatic adaptation*, which takes into consideration the case where students fail in transforming the tool into a psychological/cognitive one and do not construct new meaning.

Phase 3 of both structures serves as a connection to the theoretical field. In the techno-pedagogic task design model the theoretical field consists of deductive and inductive reasoning, which leads to developing conjectures and proofs. In the common structure of instrumentation processes, the theoretical field consists of dynamic geometry concepts or technical functioning of DGE tools, which also reflects geometrical understanding relative to DGE.

Based on the results of this study, we make the following recommendations for future research:

- Investigate whether the conceptual understanding of geometrical knowledge indigenous to the DGE developed by the students can be detached from the DGE and become formal geometrical knowledge used in other environments.
- Explore whether the three-phase model of the instrumentation process can be seen as a cycle where the newly gained conceptual understandings in phase 3 can be used later in further explorations at the first phase of heuristic application and pass again through the same phases to reach new conceptual understandings, and so forth; thus suggesting a three-phase instrumentation cycle.

*Keywords: Spatial structuring, constructions, composing/ decomposing*

### Theoretical framework

Spatial structuring, according to Battista (2008), “is the mental act of constructing an organization of form for an object or set of objects” (p.138). It consists in identifying components of shapes, establishing relationships among components into composites and establishing relationships between components, composites and the whole (Battista, 2012). Battista (2008) presents a different perspective on the development of geometric reasoning based on the idea of structuring. Spatial structuring is the first level of geometric reasoning and allows the students to understand the structures of shapes before geometric structuring, when students start to use geometric concepts.

In the early grades, constructions (composing and decomposing) and operations with shapes (geometric transformations) are special kinds of tasks that entail spatial structuring, allowing students to explore relationships among components and between components and the whole (NCTM, 2000).

According to Battista and Clements (1996), students’ spatial structuring is either local or global. Local structuring is related to the identification of components and a possible establishment of relationships among components, but students cannot yet relate components and the whole. In global structuring, students have a mental scheme for the object that enables them to establish relationships among components, composites and the whole. To a better understanding how spatial structuring is characterized, we referred to the work of Sarama and Clements (2009), related to composition and decomposition of 2D and 3D shapes, where they describe the levels of relationships students can establish among components. According to these authors, students progress along several levels: pre-composer (0-3 years old), piece assembler (4 years old), picture maker, simple decomposer and shape composer (5 years old), substitution composer and shape decomposer (6 years old), shape composite repeater and shape decomposer with imagery (7 years old) and shape composer using units of units and shape decomposer with units of units (8 years old). This progression concerning composing and decomposing also highlights a trajectory closely related to spatial structuring. In both cases, the students start by dealing with units, then they begin to establish relationships and form composites, and, in a final stage, they can deal with superunits and relate them with the whole.

### Method

This study follows a design-based research approach, where, along two cycles of research, we aim to deepen our understanding of how students develop spatial structuring of 2D and 3D shapes and

how it is related to the learning context proposed for the learning experiment. Through this, we seek to contribute to a further understanding of students spatial structuring.

The results presented in this poster concern a preliminary study, developed during the learning experiment preparation phase. This study had the purpose of testing tasks and manipulatives adequacy and of gathering some information about strategies 1<sup>st</sup> grade students use to solve the tasks. We selected one task concerning 2D shapes and, for our analysis, we compare constructions and drawings using Battista and Clements' (1996) local and global structuring, with attention to location and orientation of components.

## Results

The results of preliminary study, where students had to compose different two-dimensional constructions using four triangles, reveal that students show different levels of structuring, maybe influenced by the type of constructions and the type of components. Namely, triangles seem to present a higher level of difficulty for students, since the possibilities of combining several isosceles triangles are wider, influenced by their orientation and position.

During this preliminary study we also found differences between students' constructions using manipulatives and the drawings of their constructions. Drawing seems more demanding for students to perform, however, the search for relationships between constructions and drawings allow students to deepen their understanding about the relationships among components.

# The development of geometrical knowledge starting from arts education

*Keywords: Geometrical knowledge, Arts education, interdisciplinary tasks.*

This poster is focused on the development of students' geometrical knowledge through connections with arts education. More specifically, we present a set of didactic activities and tasks for elementary school students that involves geometry and arts, in an interdisciplinary perspective, and we also analyze and discuss their potentialities in the development of students' geometrical knowledge.

## Theoretical framework

The teaching of geometry should contribute to the development of the geometric knowledge of the students since the kindergarten, namely with regarding to the characteristics and properties of geometric forms and the relationships between them, the spatial relations and corresponding representation systems and the geometric transformations (NCTM, 2000). As Freudenthal (1973) point out "Geometry is grasping space. And since it is about the education of children, it is grasping that space in which the child lives, breathes and moves. The space that the child must learn to know, explore, conquer, in order to live, breathe and move better in it" (p. 403). In this sense, there is a dialogical relationship between the development of geometric ideas and the full exploration and experience of space. These geometrical ideas are useful in representing and solving problems in other areas of mathematics and in real-world situations (NCTM, 2000). In parallel to these ideas, research indicates that when students can recognize and use connections among mathematical ideas and can recognize and apply mathematics in contexts related with other subjects, their understanding is deeper and more lasting (NCTM, 2000). Mathematics are embedded in several tasks that students do at elementary school, so it is crucial that teachers integrate subject areas. When teachers connect mathematics with others content areas the students perceive that they explore more mathematics than they would work in a specified time only for this subject (Bamberger & Oberdorf, 2007).

## Research question and method

This poster has underlying the researches developed by two preservice elementary teachers in a context of internship (Nunes, 2017; Sobral, 2015). The goal of these researches is to describe and analyze how students deepen their mathematical knowledge and their knowledge about arts education through the exploration of tasks with interdisciplinary characteristics. From a methodological point of view, the study is of a qualitative nature (Patton, 2012). The participants are second grade students, from two classes, that solved different tasks proposed by their teachers (prospective teachers). In one of that classes were proposed four tasks that have as starting point the observation of famous artist's paintings. In the other class were also proposed four tasks, but in this case these tasks have as context the body expression activities. The data collection was realized in the probationary period, along four

weeks. The data include the solutions of the students, field notes and transcriptions videorecorder excerpts of the task's exploration in the classes.

## Results

The results revealed that (i) students increased their spatial sense, in particular they were able to identify geometric figures embedded in work of art; (ii) they had some difficulties in identifying symmetries of reflection; (iii) students produced "works of art" correctly using plastic expression techniques; (iv) students increased some geometrical ideas through the integration of movement with mathematical tasks, in particular, they were able to use geometry specific terms to describe the movements of their own body.

Summing up, it is possible to develop mathematical ideas and deepen knowledge about arts education in an articulated way. Moreover, learning through reflexive tasks about mathematics and arts education is an adequate approach in elementary school that help students to think in an integrated way.

*Our research concerns the relationship between spatial and geometrical knowledge, assuming that it is essential to have information on the children’s stored linguistic and conceptual experience associated with the terms defining geometrical concepts. This paper presents the first phase of a design experiment in which 8-year-old pupils are involved in two discussions about going straight, before and after the experience of leaving footprints. The analysis provides some elements about pupils’ conceptualization when approaching geometrical concepts.*

*Keywords: Alignment, line, linguistic, space, trace.*

### Introduction.

In Working Group 4 at CERME10 (Jones, Maschietto, & Mithalal-Le Doze, 2017) various papers focus on the relations between spatial sense, spatial knowledge and geometrical knowledge. For instance, Houdement (2017) discusses the different perspectives in which research on the relation of a subject with the world is carried out, highlighting the use of non homogeneous terminology. Other authors, as Vandeira and Coutat (2017), point out the institutional request of working on shapes and space from a perceptive approach at kindergarten and a subsequent rupture when the attention is put on geometry, above all between primary and secondary school education. In their work, they propose tasks of shape recognition in different spaces (micro-space and meso-space, following Berthelot and Salin, 1993), taking into account semiotic and manipulative aspects.

In our work, we are interested in the analysis of pupils’ construction of geometrical concepts and in the relationship between spatial and geometrical knowledge (Berthelot & Salin, 1993) at primary school in real-world experiments recalled in the call for paper of this WG4. We propose a point of view on tackling geometry at primary school, which takes into account the ways in which people communicate and think about space and shapes, both verbally and nonverbally, in order to study how to enhance geometrical understanding. For this reason, we refer to the theory of word learning (Tomasello, 2003), in which learning can be facilitated by the “exposition” to a wide range of linguistic contexts and experiences that elicitate those contexts, in order to enrich the children’s linguistic and conceptual experience and favor the construction of increasingly richer and connected semantic representations.

This paper presents a preliminary analysis of a case study, corresponding to the first phase of a design experiment on points and lines, planned in cooperation with a teacher of Italian at grade 3 of an Italian primary school.

### Research perspective.

Several studies in mathematics education concern the analysis of cognitive processes involved in mathematical thinking, paying increasingly more attention to the role of movement – considered in a

large sense, not only in gesture by hands – and conceptual constructions – as metaphors, in the learning and teaching of mathematical concepts. For instance, Nemirovsky (2003) assumes an indissoluble link between perception, motion and thinking, highlighting that perceptuo-motor activity is a constitutive element in the conceptualization of mathematics. This is reinforced by works based on a multimodal approach to mathematics knowledge and on embodied mathematics (Arzarello & Robutti, 2004). Radford (2009) highlights that mathematical meanings are constituted of actions accomplished by the subjects on material objects: thinking also occurs through a semiotic coordination of speech, body, gestures, symbols and tools. These perspectives involve an epistemological dimension related to the debate on mathematics foundations.

The next two sections present some basic components of our theoretical background: epistemological elements for mathematics, in particular for point and line, and a theory of word learning.

### Mathematics.

In his reflection on mathematics foundation, Longo (2016) proposes to avoid an axiomatic vision of mathematics, arguing that mathematics is primarily the analysis of the invariants and transformations that keep them. Following Poincaré's philosophical position, Longo states that mathematics is not grounded on arbitrary conventions, but that these conventions correspond to the most convenient choices for human beings, who live in a certain world with a specific biological structure. In this sense, mathematical concepts are constructed in the interaction between us and the world around us. In particular, Longo (1997) discusses the origin of geometry, which is considered

as a science of action and of *prediction* of movement in space: line segments, curves, circles are neither the “abstract form” (?) of a material object, nor “ideal shapes” (?), but rather the *prediction* of a path. And *a prediction is in itself an abstraction; the trajectory that is predicted or anticipated by gaze and gesture is abstract* (*Ib.*, p. 29, italic in the original text; our transl.).

In the analysis of the conceptualisation of line and point, Longo (2016) claims that: “The “big-bang” of Western mathematics is perhaps in Euclid's Definition b: *A line is a breadthless length*” (*Ib.*, p. 1, our transl.). He also suggests that it is possible to reconstruct the gesture at the core of this invention:

Such a notion of line can only be told and written, in the language, and it is the result of a philosophy of ideas, but its sense, its continuity is a practice of gesture, of drawing: if we want to understand it, we have to restart the sense, go back to the line drawn by the first teacher on the blackboard, to her/his gesture-trajectory in the space (*Ib.*, p. 2, our transl.).

Concerning the meaning of point, Longo asserts that the point in Euclid's Elements is considered as a position on a line or as the intersection of two lines, a letter of the alphabet at the ends of a segment. In this perspective, the line is not necessarily made of points, as for Cantor, since the points are “put by the geometer or obtained from lines” (*Ib.*, p. 3, our transl.). This type of analysis allows to shift the attention to the structure: the line and the point-sign are the structures at the origin of geometry. They are borderline objects, away from every tangible experience, but they exist in their relation to space referring to the experience. In his writings, Longo suggests a different perspective on mathematics, focusing not only on the objects but also on the processes of their construction.

Giusti (1999) supports the strong assumption that mathematical objects are derived by a process of “objectification of procedure” (*Ib.*, p. 26). In this hypothesis, the line could be derived by the procedure of pulling a rope between two pegs, following the rope on the ground by a stick, and the points as the positions of the two pegs on the ground.

In the educational perspective of integrating the perceptive-motor and symbolic-reconstructive modalities, Arzarello, Danè, Lovera, Mosca, Nolli, and Ronco (2012) suggest to expose students to the cognitive and cultural roots of mathematical concepts. In the analysis of the concept of line they identify three roots: symmetry, going straight and the shortest line between two points/positions.

### **Linguistics: context and contrast in the “miracle of word learning”.**

The geometrical concepts of point and line can be considered in a continuum with other concepts associated to the same terms in different contexts, as well as in actions and experiences of everyday life. In fact, when 8-year-old children meet these lexical labels at school during their first geometry lessons, they do not hear them for the first time, as they have already met them in various everyday expressions and situations, both in literal and figurative sense. Even without having any idea of what geometry is, they should for instance have some kind of conceptualization connected to the word *punto* (point), not only because they have probably learnt that it is used to refer to those small black marks that in English are called dots and spots, but also because they have met it when learning to write letters and to use punctuation (in Italian the dot on the vowel ‘i’ is called *puntino* and the word “point” is used in many punctuation marks, such as full stop or period, colon, semi-colon, exclamation and question mark, etc.), and also because of the wide use of this word in many frequent expressions, such as “meeting point”, “starting point”, “take stock of the situation” (*fare il punto della situazione*).

If we consider how children and human beings in general learn to associate meanings and concepts to lexical labels, we should not undervalue the fundamental role of the exposition to the different contexts in which words are used: as Tomasello (2003) points out, rarely do children learn words in pointing-and-naming games, with words proposed isolated from other words, as during a vocabulary lesson in a foreign language classroom. And this is particularly true if we consider that vocabulary learning does not include only concrete and content words, clearly associable to a picture, but a wider range of words and expressions, such as, for instance, prepositions or articles, and also abstract words and words used in a metaphorical way. In the process that Tomasello defines the “miracle of word learning” (*Ib.*, p. 44), most of the words are learnt by experience in everyday interactions with adults, and the children hear them used in different types of utterances and situations, mixed with other words and expressions and without special explanations by the adults. According to the so-called social-pragmatic theory of word learning adopted by Tomasello, this miracle is allowed by a series of factors. Among these, one important factor is the children’s ability to conceptualize different aspects of their experiential worlds. In later stages of word learning, when the task becomes more complex and concerns more difficult words and expressions, two other factors become crucial: “context” and “contrast”. On the one hand, children learn quite early to exploit their knowledge of the other words present in the utterance in order to understand words that they do not know; on the other hand, they also learn to use their knowledge of other words present in the utterance that might contrast with a word they do not know.

## Research questions.

Research in mathematics education investigates the relationships between physical and geometrical space, highlighting a gap in the teaching practice between an approach by physical experiences and the entrance in geometry (Kuzniak, 1995). This seems evident in some Italian textbooks, in which there is a sort of “Euclidean entrance” into the world of geometry, through the definition and representation of the fundamental geometrical entities.

Our hypothesis is that some expressions used in geometry teaching are associated with expressions and experiences in mathematical and non-mathematical contexts. In this perspective, it is essential to have information on the children’s stored linguistic and conceptual experience associated with the terms that define these geometrical concepts, considering that their conceptual representations do not necessarily coincide with the adults’ representations. This investigation is not generally carried out when the geometrical concepts are introduced to the pupils. Our broad research questions are: (a) what are the linguistic and conceptual experiences associated with geometrical concepts in 3-grade pupils before the Euclidean entrance discussed above? (b) how could those elements emerge? In other words, what kind of experiences can foster the pupils’ exposition to the different graphical, verbal and gestural representations associated with geometrical concepts?

Our working hypothesis is that the emergence of these elements can be fostered by offering educational situations in which the pupils can work in different spaces (micro, meso and macro, Berthelot & Salin, 1993), not necessarily with the teacher labelled as the mathematics teacher.

## Methods.

We have planned a design experiment composed of five phases, with physical experiences and collective discussions about them. According to the theoretical framework, after every new experience carried out with the class, the pupils should be helped to reflect and discuss on what they have done, seen and learnt, so as to re-order their mental representations and link their new conceptual experiences to their linguistic and conceptual knowledge. For this reason, class discussions are considered the central focus of all the activities that we propose.

The first phase, upon which we focus in this paper, is dedicated to “going straight”. It has been opened by a collective discussion on the pupils’ personal perception on the meaning of going straight, then the pupils have been invited to experience their ability to go straight, by leaving their footprints on a roll of paper using tempera, and finally they have been taken back to the initial question in a collective class discussion. The footprint activity has been carried out in the hall of the school, corresponding to a meso-space for the pupils. The other phases were: activities with the Bee-bot used to program paths (line and polygonal) (Phase 2); finding the shortest path between two positions by using a rope and two pegs in the macro-space of the school garden (Phase 3); activities of alignment (Phase 4); a session with a perspectograph in the lab of mathematical machines ([mmlab.unimore.it](http://mmlab.unimore.it)) on the meaning of point of view and of line as modelling the visual ray (Phase 5).

The activities were carried out in two classes (42 pupils, Grade 3, ages 8-9) in the second half of the school year. They were videotaped and all the pupils’ worksheets have been conserved. All the sessions were managed by the same Italian language teacher of the two classes, both because we were

interested in the pupils' linguistic experiences connected to geometrical concepts and we wanted to avoid that the activities were labelled as mathematical activities.

### Results and discussion: “going straight” before and after the experience.

As anticipated, this paper focuses on Phase 1 of the design experiment. In the analysis we investigate the pupils' representations associated with the expression “going straight” emerging in the two discussions before and after the experience of leaving their footprints on paper.

The discussion preceding the experience is opened by the teacher's question “If I say ‘going straight’, what does it raise in our minds?”. In the discussion the pupils describe going straight mainly as going forward without turning, changing direction, making or meeting curves, stopping, “splitting” the pathway, or without interruptions and keeping walking ignoring possible obstacles (see Figure 1 for some examples and their translation).

S.:	andare avanti però mai girare [...] avanti senza interruzioni mh senza girarsi	going forward but never turning [...] forward without interruptions mh without turning around
M.:	per me andare dritti è camminare con un criterio senza fare curve e senza fermarsi mai	to me going straight is walking with a criterion without making curves and never stopping
D.:	per me andare dritti significa che non bisogna mai cambiare la direzione e non fare curve cioè mh andare sempre in avanti	to me going straight means that we must never change direction and make curves that is mh going always forward
L.:	per me andare dritto significa non fare curve	to me going straight means not making curves
J.:	per me dritti vuol dire che andiamo dritti senza fare curve neanche ne neanche spezziamo la nostra via	to me straight means that we go straight without making curves nor e even splitting our pathway
M.:	per me dritto vuol dire andare sempre dritti senza incontrare curve	to me straight means going always straight without meeting curves
P.:	per me andar dritto è come se tu camminassi e però davanti a te ci sono degli ostacoli però tu continui a camminare [...] e continui ad andare dritto	to me going straight is as if you walked but in front of you there are obstacles but you keep walking [...] and keep going straight

Figure 1. Examples of definitions of “going straight”

The pupil who first enters the discussion is the only one who mentions a starting and arriving point, talking about a person going from one point to another. Besides, only one of the pupils, F., mentions the use of a ruler, by comparing natural entities such as a lake or a river, which “are round or make curves”, to lines drawn with a ruler, which “are not curves”: “to me going straight means ... for instance ... let's look at a lake or a river which are round or make curves ... on the contrary when you use a ruler you draw a straight line ... it is not a curve”.

Most of the descriptions, therefore, seem to suggest the children think about going straight focusing their attention on the movement in itself and on what they have in front of them when they go straight, more than on the (concrete or ideal) line that one draws when he/she goes straight. These kinds of description are consistent with our theoretical background: the conceptualization of going straight is not mediated yet by school geometry and it is connected to everyday experiences and to body movement. In particular, on one side, it reflects a conceptual representation connected to an embodied experience which involves an interaction between us and the world around us, on the other side, from a more linguistic point of view, it recalls everyday expressions such as “going straight home”, as a synonym of “going directly”, and “going straight to the point”, that is without interruptions or

deviations. It is in this sense, in our opinion, that expressions such as “interruption” or “obstacle” should be interpreted in the pupils’ definitions.

It is quite important for the teacher to collect this kind of information, because it provides a starting point upon which the following part of the experience should be based and built. Even if here we have no space to go into the details of the footprint activity, aimed at helping the pupils to experience their ability to go straight, we would like to mention that the activity starts in fact from the teacher’s invitation to see what happens and what one does when he/she tries to go straight, and that during the activity the teacher progressively tries to lead the pupils to shift their attention from the movement in itself to the traces left with the colored footprints.

Another aspect that can be mentioned here only briefly is the children’s use of gestures. Even if we have noticed that they generally tend not to use gestures, in some few cases they do, and their gestures help to understand their conceptions even in the absence of labels and other clear verbal expressions. The most interesting example concerns D., who intervenes in the discussion at two different points, in both cases helping himself with gestures, once adding also some “sound effects”, probably to convey swiftness as well as straightness. So, when D. says that going straight means that you should never change direction nor make curves and keep going forward (see D.’s intervention in Figure 1), while saying “keep going forward” he moves his right arm forward, upon the school desk, with flat hand and lateral palm. Then, quite interestingly, when F., speaking immediately after him, compares round and curvy lakes and rivers to straight lines made by a ruler, D. echoes F.’s definition of round and curvy by drawing an imaginary circle on the desk with his right forefinger and accompanying this movement making a circle also with his shoulders, while he puts both hands in a flat position with the palms oriented one towards the other when F. mentions the ruler. Finally, towards the end, D. enters the discussion again to give a specification about the meaning of going straight as not making curves, putting together the concepts of “curve” and “direction”: “that is eh, .. you don’t have to make round curves, but you can do so [...] doing the tips as well” (D.). The two gestures that he produces as if drawing on the desk to illustrate what one cannot do (round curves) and one can do (tips) make it clear that he has in mind the distinction between a round line and the representation of a polygonal with points, in which the change in direction corresponds to the meaning of angle. Even if the teacher has no time to deepen this aspect, she asks the pupil to describe how the tips are and D. limits himself to repeat the imaginary drawing, this time in the air and not on the desk, maybe in order to be seen better by the teacher, but adding a level of abstraction.

In the class discussion following the experience, the teacher starts with the same question she had asked in the discussion preceding it and tries to induce the pupils to relate their understanding of going straight with the activity just carried out.

After the experience, going straight is defined mainly as “without curves”, with its variants “crookedly” and “without zigzagging”, or as “without interruption”.

In the discussion, the teacher fosters the interpretation of “without interruption” by relating it to the two different kinds of footprints left by the pupils, attached one to each other so as to trace a line, or far from each other as in a normal walking. This way, the experience helps the teacher to shift the attention from the straight movement in itself to the trace of its trajectory and to the footprint line,

which one girl then defines as “a line made by our footprints” (*è una linea fatta dall'impronta dei nostri piedi*).

The change of direction and the representation of a polygonal are, in a certain way, more specified than in the discussion before the experience, even if only one pupil explicitly refers to the angle. The main element in the pupils' comments concerns keeping going straight after the turning point and being able to “go straight in many different directions” (*puoi andare dritto in tante parti diverse*). In this case, the interruption is interpreted in terms of changing direction.

Moreover, the work on the meso-space provides also a more tangible representation of going straight which can be used to introduce new kinds of reflections. For instance, with reference to the presence of an obstacle in the direction of movement, invited by the teacher to recall the “special solution” proposed by one girl during the activity in order to go straight on a road presenting an interruption, the pupils explicitly speak about “going back” and about “going forward and backward” followed by the specification “on the same line”.

The experience of going straight leaving footprints provides, therefore, a spatial context in which the movement can be seen and performed in the same way at different times (during and after the experience). This graphical object could have been exploited even more by the teacher, for instance to control if the movement was straight or not by checking the alignment of pupils' footprints. It is a task that could be proposed in a next experiment.

In this discussion, the line comes out also to describe one of the strategies used during the experience to go straight. When walking on the paper the kids did not control the trace directly by looking at it, but seemed to rely more on their bodies and sense of equilibrium, on the help of other pupils or on other. One of the pupils, invited by the teacher to recall what he had said during the experience about a line he was following, says that while he was walking he could “see the line in his head” because he was “imagining something like a road next to him” and then he was “staring at a fixed element, a line, which had the same shape as a road”.

This idea of imagining a line in your mind may imply a greater engagement of cognitive control, which two pupils seem to refer to when they mention the difficulty of the task of going straight and the need for concentration when doing it, compared to when making curves.

Finally, to make at least one reference to gestures, we would like to mention the control of alignment by view spontaneously proposed by F., who is the pupil who had already used many gestures in the initial discussion. During the experience he had described (and shown) his strategy to verify the straightness of the footprint line on paper by aligning in front of one eye his outstretched arm and the corresponding shoulder, with the other eye closed. In the discussion after the experience the teacher invites him to recall that gesture and the same gesture is then imitated by another kid.

### **Concluding remarks.**

The analysis of the two discussions preceding and following the experience of leaving footprints on paper in the first phase of the design experiment provides various data on the conceptual representation of “going straight” that 8-year-old children might have before starting to study geometry and on how these representations, together with an experience which involve their bodies

and the meso-space, can provide the basis to reflect on the concept of going straight and begin to introduce the concept of line.

*The aim of the study is to investigate the creativity demonstrated by students in multiple-solution tasks (MSTs) in geometry taking into account the role of geometrical figure. To this end, the test that was administered among 149 eleventh graders consisted of two types of problems: a. with and b. without the relevant figure. Findings revealed that fluency and flexibility were higher when the verbal description of the problem was accompanied by the relevant figure. The originality of students' solutions, though, did not differ in the two types of problems. The similarity analysis suggested distinct student profiles: (a) poor fluency and flexibility, (b) moderate fluency and flexibility and (c) high fluency and flexibility. Although the majority of students belong to the first two groups, qualitative results provide evidence that students managed to improve and gain high fluency and flexibility. Findings also indicated that geometrical figure apprehension is a prerequisite for high levels of creativity in geometry.*

*Keywords: Creativity, geometry, multiple-solution tasks (MSTs), geometrical figure apprehension.*

### Introduction and Theoretical Framework

Creativity has been proposed as one of the major components to be included in Mathematics education, since “the essence of Mathematics is thinking creatively” (Mann, 2006, p. 239). Torrance (1994) defines creativity as multidimensional; fluency, flexibility, originality (or novelty) and elaboration are aspects of creativity. Fluency is related to the flow of ideas, flexibility has to do with the ability to shift between different ideas, novelty is associated with the originality of the individual's ideas or products, and elaboration is associated with the individual's ability to describe, illuminate, and generalize those ideas. A number of researchers (e.g. Silver, 1997; Stupel & Ben-Chaim, 2017) suggest that linking mathematical ideas using multiple approaches to solve problems (or prove statements) is essential for the development of mathematical reasoning and fosters better comprehension and increased creativity in Mathematics. Following Torrance, Silver (1997) claimed that in order to develop creativity by means of problem solving it is necessary to advance three components of creativity. Fluency is promoted by raising multiple ideas for the solution of one problem. Flexibility is raised when after one solution is already in hand, the individual searches for more possible solutions. Originality is developed when an individual succeeds in generating a new solution, in addition to those known to him/her at the time.

Geometry provides opportunities for investigation and proving activities that resemble the work of mathematicians (Herbst, 2002). The usefulness of geometrical figures in problem solving in geometry

is beyond doubt as they provide an intuitive presentation of all constituent relations of a geometrical situation (Duval, 1995). Duval (1995) distinguishes four apprehensions for a geometrical figure: perceptual, sequential, discursive and operative. To function as a geometrical figure, a drawing must evoke perceptual apprehension and at least one of the other three. Each has its specific laws of organization and processing of the visual stimulus array. In particular, perceptual apprehension refers to the recognition of a shape in a plane or in depth. Perceptual apprehension indicates the ability to name figures and the ability to recognize several sub-figures in the perceived figure. Sequential apprehension is required whenever one must construct a figure or describe its construction. The organization of the elementary figural units does not depend on perceptual laws and cues, but on technical constraints and mathematical properties. Discursive apprehension is related to the fact that mathematical properties represented in a drawing cannot be determined through perceptual apprehension. In any geometrical representation the perceptual recognition of geometrical properties must remain under the control of statements (e.g. definitions). However, it is through operative apprehension that we can get an insight into a problem solution when looking at a figure. Operative apprehension depends on the various ways of modifying a given figure: the mereologic, the optic and the place way. The mereologic way refers to the division of the whole figure given into parts of various shapes and the combination of them in another figure or sub-figures (reconfiguration), the optic way is when the figure is made larger or narrower, or slant, while the place way refers to its position or orientation variation. Each of these different modifications can be performed mentally or physically through various operations. These operations constitute a specific figural processing which provides figures with a heuristic function. One or more of these operations can highlight a figural modification that gives an insight into the solution of a problem in geometry.

MSTs contain an explicit requirement for solving them in multiple ways. A number of studies (e.g. Levav-Waynberg & Leikin, 2009) used MSTs as an instructional tool for developing knowledge and creativity, as well as a tool for the evaluation of creativity in geometry. Moving a step forward, the present study aims to shed new light as far as MSTs are concerned on evaluating and developing creativity in geometry taking into account the role of geometrical figure. As there is a need for a multidimensional approach as far as teaching and learning in geometry is concerned, we address the following research questions (RQ): (a) what is the influence of geometrical figure apprehension on the production of multiple solutions in geometry problems? (b) what kind of creativity (fluency, flexibility, originality) do students demonstrate when working with MSTs in which the geometrical figure is either given or not in the wording of the problem? (c) what are students' profiles, if any, in terms of the number of solutions in MSTs in geometry?

## Methodology

A written test was administered among 149 eleventh graders (77 boys and 72 girls) as follows: 147 of the students completed the test in usual classroom conditions and 2 students took part in an individual interview during the solution process of the test. The test consisted of four geometry problems that were content and face validated by two experienced Mathematics school teachers in secondary education and two professors of Mathematics Education. The students were asked explicitly to solve them in as many ways as possible. In problems 1 and 3 the wording of the problem was accompanied by the relevant figure, while in problems 2 and 4 only the wording of the problems

was given. The duration of the test was 110 minutes. It is worth mentioning that the problems (without the relevant figure) were piloted among a small number of students before the final administration of the test. It was confirmed that all the problems (without the relevant figure) had the same level of difficulty.

<p><b>Problem 1:</b> Prove in as many ways you can that, that the median drawn to the hypotenuse of the right triangle equals half the hypotenuse.</p> 	<p><b>Problem 3:</b> Let a rectangular triangle ABC (<math>B = 90^\circ</math>), D midpoint of segment AB, E the midpoint of segment AC and Z the midpoint of segment BC. Prove in as many ways you can that <math>DZ = EB</math>.</p> 
<p><b>Problem 2:</b> AB is a diameter on a circle with center O. D and E are points on circle O so that <math>DO \parallel EB</math>. C is the intersection point of AD and BE. Prove in as many ways as you can that <math>CB = AB</math>.</p>	<p><b>Problem 4:</b> Find the center of a circle in as many ways as you can, if you only know the circumference of the circle.</p>

**Figure 1. The four geometry problems**

The solutions provided by the students were classified in view of the strategy they used. Then, the aspects of creativity (fluency - flexibility - originality - total creativity) were calculated based on the scoring scheme that Leikin (2009) proposed for the evaluation of performance on MSTs. The construct of solution spaces that will be explained in the next section was also used to analyze the student problem-solving performance (Leikin, 2007). In order to answer the research questions, descriptive statistics and t-test at 95% significance level were used. Furthermore, a similarity statistical analysis was conducted using the computer software C.H.I.C. It is a method of analysis that determines the similarity connections of the variables (Gras, Suzuki, Guillet, & Spagnolo, 2008). On the similarity diagram we symbolize with  $P_i$ ,  $i=1, 2, 3, 4$  the problem referred to and symbolize with  $S_j$ ,  $j=0, 1, 2, 3, 4$  the number of solutions for each problem. The interviews with the two students and one of the authors were transcribed and examined qualitatively.

## Results

In order to examine the influence of geometrical figure apprehension in the development of mathematical creativity, five solutions which were provided by students in problem 2 are presented in Figure 1. These solutions are grouped into three solution spaces based on the strategies and properties that students used. In the first solution space, the main strategy is that the straight line joining the middle of the two sides of a triangle is parallel and equal to half of the opposite side, and includes two solutions (1a, 1b). The first solution was found by 8.1% of the students while the second solution which requires drawing an auxiliary line was only found by the 2.7% of students; the originality of this solution space rated 10 ( $10.8\% < 15\%$ ). In the second solution space, the main strategy is that equal corners were formed, and refers to two solutions (2a, 2b). These solutions were provided by the 28.4% of students as it did not require any auxiliary construction. Its originality rated

0.1 (56.8% > 40%). The third solution space includes one solution (3) that refers to the construction and the use of the rhomb properties. This solution which requires constructing an auxiliary line was provided only by 1.4% of the students and the originality rated 10 (1.4% < 15%). As far as the fluency for problem 2 is concerned, 41.5% of the students were unable to solve the problem, while a similar percentage of students (49%) found only one way of solving it. The percentage of students who were able to find 2 or 3 ways was quite low (9.5%).

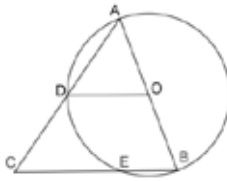

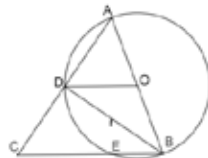

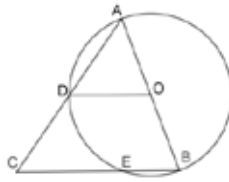

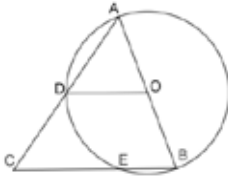

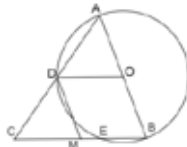

<p><b>1a Solution</b> 8.1%</p> <p><math>DO = 1/2AB</math>, as equal radii in a circle. <math>\Rightarrow DO</math> is a midline in triangle <math>ABC</math>, as parallel to <math>BC</math> and bisecting <math>AB</math>. <math>\Rightarrow DO = 1/2AB = 1/2BC \Rightarrow AB = BC</math>.</p> 	<p><b>1b Solution</b> 2.7%</p> <p><math>D</math> is the mean of the <math>AC</math>, since <math>DO</math> joins the medium <math>C</math> with <math>D</math> and <math>OD \parallel BC</math>. We construct the median <math>DB</math> of the triangle. The angle <math>D1</math> goes to a semicircle so <math>D1 = 90^\circ</math>. Thus, <math>DB</math> is both median and altitude of the triangle <math>ABC</math>. Therefore, <math>ABC</math> is isosceles and <math>AB = CB</math>.</p> 	
<p><b>2a Solution</b> 28.4%</p> <p><math>DO = AO</math>, as equal radii in a circle. <math>\Rightarrow \angle ADO = \angle A</math>, as base angles in an isosceles triangle, <math>\angle ADO = \angle ACB</math>, as equal corresponding angles within parallel lines, <math>\angle ACB = \angle A \Rightarrow AB = BC</math>, a triangle with 2 equal angles in isosceles.</p> 	<p><b>2b Solution</b> 28.4%</p> <p><math>DO = AO</math>, as equal radii in a circle. <math>\Rightarrow \angle AOD = \angle ABC</math>, as equal corresponding angles within parallel lines. <math>\Rightarrow \angle A = \angle A</math>, as shared angle <math>\Rightarrow \triangle AOD \sim \triangle ABC</math> (2 equal angles) <math>\Rightarrow AB = BC</math> (a triangle similar to an isosceles triangle is also isosceles).</p> 	<p><b>3 Solution</b> 1.4%</p> <p>We construct a parallel line from <math>D</math> to <math>AB</math>. Taking into account that it passes through the median <math>D</math> of the <math>AC</math>, it also passes from the median <math>M</math> of <math>BC</math> and <math>MD = AB/2</math>. <math>EB \parallel DO \Rightarrow MB \parallel DO</math>. Therefore, <math>MB = DO = BC/2</math> and <math>OD = OB</math> as the radius of the circle. Then, <math>DOBM</math> is a rhombus <math>\Rightarrow OB = MB \Rightarrow 1/2AB = 1/2BC \Rightarrow AB = BC</math>.</p> 

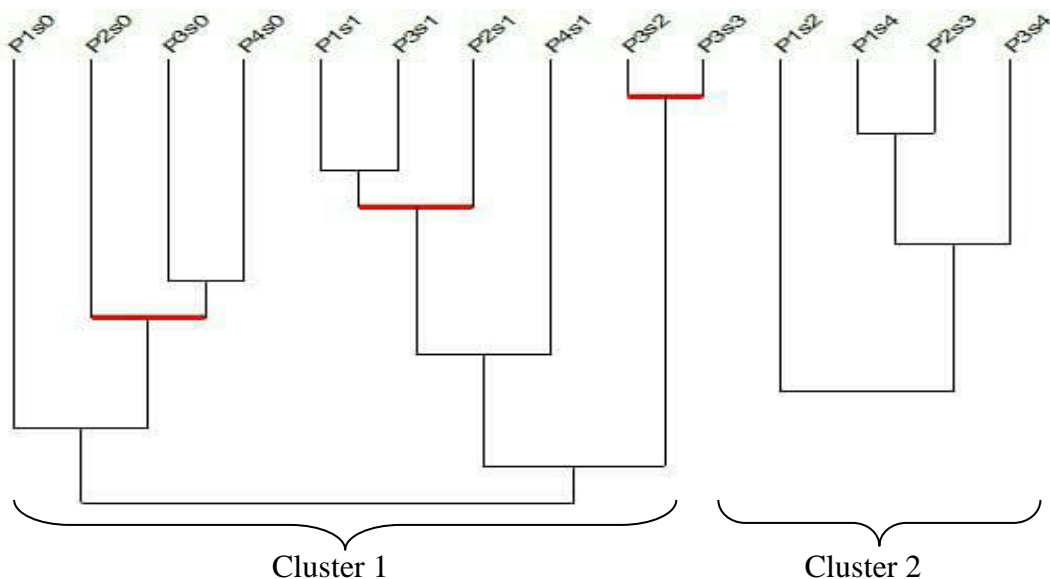

Figure 2. Collective solution spaces for problem 2

Students who produced solutions 1a, 2a and 2b possess at least three kinds of geometrical figure apprehension. In particular, the students apprehend sequentially the figure as they construct the figure from scratch by organizing its elementary units through constructive constraints and mathematical properties. Furthermore, the students have a perceptual apprehension, since they recognize the various subfigures in the circle and the inscribed triangle. They also have discursive apprehension, since they prove the solution of the problem based on theorems. In order to produce solutions 1b and 3, except the other three types of geometrical figure apprehension, operative apprehension is required as well,

since the students have to construct the auxiliary lines for the construction of the median of the triangle and the construction of the rhomb to find the solution of the problem. It is evident that a geometrical figure can be constructed in many ways (mereologic modification), each of which can lead the student to a different solution of the problem. Nevertheless, from the solutions given by the students we observed that some students construct the same auxiliary line but they solve the problem differently. In fact, students apprehend operatively the figure in the same way but have different discursive figure apprehension as for the same auxiliary structure they use different properties and theorems to find the solution.

On the basis of the results of the t-test, the number of solutions (fluency) that students give to problem 1 and 3 ( $M = 2.16$ ,  $SD = 1.42$ ), in which the problems are accompanied by the relevant figures, are statistically bigger ( $t = 6.02$ ,  $df = 146$ ,  $p < 0.001$ ) than those that students give to problems 2 and 4 ( $M = 1.44$ ,  $SD = 1.21$ ) in which the figures are not given. Concerning flexibility of the solutions to the problems in which the figure is given ( $M = 19.88$ ,  $SD = 12.65$ ), and the problems without the corresponding figure ( $M = 13.93$ ,  $SD = 11.37$ ), significant differences are indicated with an apparently higher score in the problems in which the figure is given ( $t = 5.57$ ,  $df = 146$ ,  $p < 0.001$ ). Even though according to the findings students' fluency and flexibility is higher in problems in which the figure is given, this is not the case with the originality of the solutions ( $t = -1.87$ ,  $df = 146$ ,  $p > 0.05$ ) and total creativity ( $t = -0.71$ ,  $df = 146$ ,  $p > 0.05$ ).

In fact, there are not any significant differences as far as originality and creativity are concerned in the two types of problems.

**Figure 3. Similarity diagram of students' number of solutions**

In the similarity diagram, which concerns students' ability to produce various solutions, there are two significant clusters. Cluster 1 consists of two sub-clusters. The first sub-cluster includes the variables P1s0, P2s0, P3s0, and P4s0. It refers to students who do not give any solution to any of the problems, regardless of the presence of figure or not. The second sub-cluster (P1s1, P2s1, P3s1, P4s1) is related to students who solve all problems in one way, regardless of whether the figure is given or not. In the second sub-cluster the solutions belong to one solution space. This sub-cluster is associated with the

variables P3s2, P3s3 that involve students who have solved the third problem in which the figure is given, in two or three ways, providing evidence that the figure affected its level of difficulty.

Cluster 2 contains the variables P1s2, P1s4, P2s3, and P3s4 that correspond to the students who are highly fluent and flexible in their solutions. On the one hand, these students give two, three or four solutions which mean they have the fluency to produce multiple solutions. On the other hand they are able to move from one solution to another, using different mathematical properties and representations as their solutions belong to at least two different solution spaces.

In fact, the results suggested that the participants of the study form three distinct student profiles:

- Profile 1: Students with poor fluency and flexibility (0 solutions)
- Profile 2: Students with moderate fluency (1-3 solutions) and flexibility (1 solution space)
- Profile 3: Students with high fluency ( $\geq 2$  solutions) and flexibility ( $\geq 2$  solution spaces)

The majority of the students have poor and moderate fluency and flexibility. In particular, fifty students (34%) have poor fluency and flexibility in at least one problem, sixty six students (45%) provide only one solution in at least one problem and twenty five students (17%) solve one of the problems in two different ways at least. Only six students (4%) have high fluency and flexibility in at least one problem.

The qualitative data provided further insight in to students' potential performance. During the solution process, changes concerning fluency and flexibility of student solutions were observed. The following extract from one of the student's interview (Student A) is indicative::

10. St: I'm not so good at geometry.

17. St: Better find another student who knows them better. I do not remember them at all.

19. St: Okay, I leave the first problem and go to the third problem.

*(Having already found two ways in the first problem after solving the other three problems)*

165. St: Let me think... I have an idea, half a minute to see something in the third problem.

166. St: Construct a parallel line from C to AB and from B to AC and create a rectangle for  $A = 90^\circ$  (the student is drawing the new figure). From this I will say that the diagonals of the rectangle are equal and bisected. Therefore,  $AD = 1 / 2BC$ .

170. St: I thought of something else.

172. St: Could I construct a circle as we did in the forth problem? Because the right angle ends in a semicircle, let's say that BC will be a diameter and the center will be D. So DC, DB and DA will be radiuses, so they will be equal.

It is evident that, MSTs enhance flexibility in geometric knowledge and student thinking as they encourage connections between different ways of solving them. The student, as soon as he had solved the problems, moved from zero fluency and flexibility during the solution of the first problem to high fluency and flexibility of solutions at the end of the interview. During this process he often made references to the previous problem solutions. It is worth mentioning, that the qualitative data strengthen quantitative results as the construction of auxiliary lines and reconfigurations that reflect

the operative figure apprehension revealed to be the most important aspects for producing new ways of solving and achieving high levels of creativity in geometry.

## Discussion

The present study explored students' creativity in MSTs using a multidimensional approach as the following dimensions are considered: (a) mathematical creativity; (b) geometrical figure apprehension; and (c) multiple-solution problem solving in mathematics education. Significant differences in the fluency and flexibility of student solutions were observed depending on whether or not the figure was given (RQb). In fact, students exhibited greater fluency and flexibility in the problems in which the verbal description of the problem was accompanied by the relevant figure. As far as the originality and the total creativity of students' solutions are concerned, they did not differ significantly in the two types of problems. On the one hand these findings are explained taking into account that even though flexibility and fluency are different aspects of creativity, they are strongly related to each other (e.g. Leikin, 2009). On the other hand, researchers (e.g. Levav-Waynberg & Leikin, 2012, Leikin, 2013) pointed out that originality is a more internal characteristic than fluency and flexibility. It is also more related to creativity but less dynamic.

The similarity analysis of the number of student solutions suggested three distinct profiles of students: (a) a poor fluency and flexibility group; (b) a moderate fluency and flexibility group; and (c) a group of high fluency and flexibility (RQc). The majority of students belong to the first two groups. However, qualitative results provide evidence that students managed to move from poor to high fluency and flexibility of solutions through references to previous problems they had solved. This is in line with Leikin's (2013) findings that fluency and flexibility are dynamic, whereas originality is a "gift". As our work deals with relative creativity (Leikin, 2009), we support that mathematical creativity should be developed in all students (Sheffield, 2009). As a matter of fact, creativity is influenced by the teaching, guidance and experiences of the individual (Silver, 1997). Thus, the systematic exploitation in the teaching of MSTs in geometry may enhance student fluency and flexibility.

Furthermore, emphasis should be given to activities that help students overcome the perceptual way of looking at a geometrical figure and moving to operative figure apprehension. The results suggest that the students who apprehend the figure operatively are able to undertake mereologic modifications that enable them to provide different proofs in geometrical problems (RQa). An interesting finding which highlights heuristic functioning of figures is that some students use the same auxiliary construction but their solutions are based on different properties and theorems. In other words, they have the same operative apprehension but different discursive apprehension of a figure. Indeed, operative apprehension of a figure is a source of creativity in geometry as it gives insight into the solution of the problem. Nevertheless, Duval (1995) indicated that the mathematical way of looking at figures only results from the coordination of separate processes of apprehension over a long time. In line with this assertion, our findings revealed that geometrical figure apprehension is a prerequisite for students to provide a variety of solutions to the geometry problems and, thus, have high creativity.

Certainly, there is still need for further investigation into the teaching implications of the subject. In the future, it would be interesting and useful to examine the effects of intervention programs aiming

at developing geometrical figure apprehension in view of MSTs. Furthermore, the validation of a theoretical model that examines the structure and relation of various components of geometrical figure apprehension, mathematical creativity and ability to prove in multiple ways would contribute to this domain of research too.

*The present research examines middle school mathematics teachers' conceptions of geometric definitions, and specifically whether they possess geometric conceptions at the van Hiele fourth level. Sixty two teachers participated in the research. We used an open-ended questionnaire for data collection. The questionnaire included three questions concerned with the equivalence between definitions, sufficient and necessary conditions, and deductive geometric reasoning related to definitions. We used deductive and inductive content analysis to analyse the data. We found that generally, the participating teachers did not possess the geometric conceptions at the van Hiele fourth level and had difficulties in understanding what the imperative and optional features of mathematical definitions are. In addition, the participants' conceptions of definitions have specific features that explain why they have not attained the van Hiele fourth level.*

**Keywords:** *Conceptions, parallelogram, definitions, in-service teachers*

## Introduction

Definitions are used as building blocks for the construction of mathematical theorems (Pimm, 1993), which makes them play a central role in building understanding of the meanings of mathematical concepts (Wilson, 1990). According to van Hiele and van Hiele's (1958) theory about geometric thinking development, at the informal deduction level, the learner understands the importance of precise definitions, how a particular attribute derives from another, and the inclusion relationship between groups of shapes; the learner can construct internal connections between the different properties of the same shape and connections between the properties of different shapes. At the subsequent level; that the formal deduction level, the learner understands the role of definitions and recognizes the features of a formal definition, such as necessary and sufficient attributes and equivalent definitions. At this more advanced level, the learner understands the functions of definitions, axioms and theorems as a deductive chain.

Zaslavsky and Shir (2005) distinguish between two features of the definition: those which are imperative and those which are optional. Some of the imperative features of definitions are their being non-contradicting, unambiguous and hierarchical, while some of the optional features of mathematical definitions is the requirement about their being minimal; in other words include a minimum of sufficient attributes of the concept. In addition to the aspect of imperative and optional features of definitions, van Dormolen and Zaslavsky (2003) mention four criteria for logical necessities of definitions; one of them is the criterion of equivalence. Other criteria are part of general culture but are not necessary from logical perspective, such as the criterion of minimality and the criterion of elegance, which we need when we want to choose between two equivalent definitions. Using these criteria, we take the 'nicer definition'; the one has less words and less symbols and uses

more general basic concepts. Empirical research shows that many mathematic educators prefer mathematical definitions to be minimal and elegant or parsimonious (Vinner, 1991; Van Dormolen & Zaslavsky, 2003; Leikin & Winicky-Landman, 2001). On the other hand, there are those who, in certain cases, also prefer a non-minimal definition (de Villiers, 1998; Pimm, 1993; van Dormolen & Zaslavsky, 2003; Zaslavsky & Shir, 2005). For example, it is possible to define two similar triangles as two triangles in which two angles in one triangle have equal angles in the second triangle. From the pedagogically perspective, adherence only to the minimal definition, may impair the understanding of the concept of similar triangles (Zaslavsky & Shir, 2005).

One feature of mathematical definitions appreciated by mathematicians and mathematics educators is the equivalence of definitions of the same concept (Harel, Selden & Selden, 2006). Leikin & Winicky-Landman (2001) studied mathematical definitions in a non-geometric context, and found that many high school teachers did not notice that a particular concept could be defined in a number of equivalent ways. When the learner attends to the equivalent definition, he/she performs in van Hiele informal deduction level. Haj Yahia, Hershkowitz & Dreyfus (2014) found that many senior school students rejected correct geometric proofs because they failed to notice that there might be more than one definition for a particular concept. When we attend to the equivalent geometrical definitions, however, we perform as expected in van Hiele & van Hiele (1958)'s informal level: we accept the notion that we can derive one attribute from the other/s. For example, if in a quadrilateral every two opposite sides are parallel, then we can deduce that every two opposite sides are equal and vice versa – and these two statements are equivalent.

Another important aspect of definitions is giving a definition that contains non-sufficient attributes (de Villiers, 1998). Many studies reported that when the students asked to define some quadrilaterals a part of the students gave brief definitions but not complete (de Villiers, 1998; Choi, Oh & Kyoung, 2008; Markovic & Romano, 2013). de Villiers (1998) reported that when the students asked to define the rhombus, a part of the students gave brief definitions but not complete. For example, a rhombus is a quadrilateral whose diagonals are perpendicular to each other. Markovic & Romano (2013) reported that some students define the square as "a geometric figure all four sides of which are equal".

## **Research rational and goals**

Since the progress from one level to another on van Hiele and van Hiele's (1958) depends more on teaching than on age or biological maturity, different types of instruction can have a different effect on the progression from level to level. In order to prove and to be able to understand the role of proof, he/she must be at the formal deduction level. Moreover, teachers' conceptions are the basis for their mathematics teaching (Johnson, Blume, Shimizu, Graysay, & Konnova, 2014), especially their teaching of geometry. Thus investigating the teachers' conception about mathematical definition plays central issue in the teaching processes. The teachers are expected to be at the formal deductive level, where they understand the role of definitions and recognize the logical features of a formal definition, such as necessary and sufficient attributes and equivalent definitions. In addition, they are expected to know the imperative features and the optional features of definitions (Zaslavsky & Shir, 2005).

The present research intends to examine mathematics teachers' conceptions of geometric definitions. The results of the research would make us more knowledgeable regarding these conceptions, and in

particular regarding the features of these definitions. This is especially needed because of the little research done on teachers' conceptions of a basic aspect of their ability to teach geometry; i.e. geometric definitions.

## **Research question**

What are the features of middle school teachers' conceptions of geometric definitions?

## **Methodology**

Sixty-two in-service middle school mathematics teachers who constitute theoretical sample (Glaser & Strauss, 1967) participated in this study. These teachers studied for completing their M.Ed. (Master of Education) degree in mathematics education in an academic college for teachers. We used an open-ended questionnaire for data collection. The questionnaire included three questions that are concerned with the following topics related to definitions: the equivalence between definitions of the same concept, sufficient and necessary conditions of a concept, and finally deductive geometric reasoning related to definitions. To provoke teachers' thinking, we used prompts consisting of fictive or real contradicting statements of students that represent common conceptions of definitions of geometrical concepts. The participating pre-service teachers were asked to fill the questionnaire, by commenting on each statement; whether they agree with it or not, and to explain their answers.

For analysing the data, we used a qualitative coding method (Salanda, 2015) that is close to grounded theory (Glaser & Strauss, 1967). We used deductive codes derived from a theoretical perspective (Charmaz et al., 2007) and inductive codes for the themes not present in existing research about geometric education. Using the deductive codes, we characterized the answer of each participant according to its satisfaction of the aspects of definition: being minimal, being hierarchical, awareness of sufficient conditions, awareness of equivalent definitions, etc. Afterwards we looked at shortages of the participants' conceptions, for example being aware of the sufficient conditions but enforcing other conditions. Next we looked at the reasoning behind the answer, for example being not aware of equivalence definitions as a result of considering the lack of the 'edges' term.

The coding was conducted independently by the three authors. The inter-rater reliability of coding by Cohen's Kappa was 0.86, which shows an appropriate value of the interrater reliability.

## **Results**

This section is splitting into four parts. We present the results concerning (a) the equivalence between definitions, (b) sufficient and necessary conditions, and finally (c) the deductive geometrical reasoning.

### **The equivalence between definitions of the same concept**

The first item in the questionnaire related to the following question:

*The mathematics teacher asked his students to define the "parallelogram".*

***Sami** defined the parallelogram as "Parallelogram is a quadrilateral in which every two opposite sides are parallel". **Rami** defined the parallelogram as "Parallelogram is a quadrilateral in which every two opposite angles are equal". **Rafi** defined the parallelogram as "Parallelogram is a quadrilateral in which the diagonals crossing each other" **Salim** defined the parallelogram as "Parallelogram is a quadrilateral in which every two opposite sides are equal". **For each of these claims you need to determine whether it is a definition and explain your response.***

Answering the first item, 25.5 % (16) of the participants demonstrated knowledge of equivalent definitions. 14.5% of the participants, though they demonstrated knowledge of equivalent definitions, preferred some of these definitions over others. Specifically, these students preferred the definition of the parallelogram that included properties about the sides of the parallelogram, probably because the name indicates that the sides are parallel. Three of them preferred the definition that mentions the property of “pairs of opposite sides being parallel”.

27.5% (17) of the participants claimed that the definition should include conditions about sides of a parallelogram, but did not demonstrate knowledge of equivalent definitions. These students were not satisfied with the definition that includes just the term ‘angles’ or ‘diagonals’, but wanted the definition statement to include conditions about the sides. Eight of these students even wanted the statement to include conditions related to two components; sides and parallelism. One student wrote, *“This could not be a definition of the parallelogram, for it just talks about angles”*.

The previous results indicate that the need for a condition about the sides of the quadrilateral or/and the opposite sides being parallel was mentioned by the students who demonstrated knowledge of equivalent definitions and those who did not demonstrate such knowledge.

27.5% (17) of the participants differentiated between definitions and properties. Doing so, they did not accept the statements that describe the parallelogram in terms of its angles or diagonals as definition, saying that it is property and not a definition. Five of these students did not elaborate further. For example, one of them wrote, *“This is not a definition because it is a property”*. The rest of these students (twelve students) argued that the definition should talk about sides and not any other element of the parallelogram. One of them wrote, *“This is a property and not a definition of a parallelogram for it includes information about the angles and not the sides”*.

19.5% (12) of the participants did not accept a statement as a definition because of their little understanding of the sufficient conditions issue of the definition. These students did not accept the property “each pair of opposite sides are parallel” as sufficient for a quadrilateral to be a parallelogram. Instead, they suggested that the correct definition should include also the equality of the edges. One of these students wrote, *“the definition should be a parallelogram is a quadrilateral that each pair of its opposite sides are parallel and equal”*.

For the first item only and because of the various percentages in its results, we will summarize these results in Table 1 to make them more accessible.

Category	Percent
Demonstrating knowledge of equivalent definitions	25.5%
- Preferring definitions that included properties about the sides	
Not demonstrating knowledge of equivalent definitions	
- Preferring definitions that included properties about the sides	27.5%
- differentiating between definitions and properties	27.5%
- little understanding of the sufficient conditions	19.5%

**Table 1: Categories of students' responses on the equivalence item and their percentages**

### Sufficient and Necessary conditions of a concept

The second item in the questionnaire related to the following question:

*The mathematics teacher asked his students to define the "parallelogram".*

***Sami** defined the parallelogram as "Parallelogram is a quadrilateral in which every two opposite sides are parallel". **Rami** defined the parallelogram as "Parallelogram is a quadrilateral in which two opposite sides are parallel". **Rafi** defined the parallelogram as "Parallelogram is a quadrilateral in which every two opposite sides are parallel and equal" **For each of these claims you have to determine whether it is definition And to explain your response!***

Answering the second item, 82% (51) of the participants did not consider correctly that the statement "The parallelogram is a quadrilateral in which two opposite sides are parallel" an accurate definition of the parallelogram. Twenty-four of them reasoned that the statement should include 'all opposite sides' and not just two opposite sides. The rest (twenty-seven students), in considering the statement not an accurate one, reasoned that the statement describes a trapezium and not a parallelogram. Eleven students wrote that the statement is an accurate statement because it talks about the opposite sides being parallel.

87% (54) of the participants considered correctly, "The parallelogram is a quadrilateral in which each pair of opposite sides are parallel" an accurate definition of the parallelogram. Eight students considered this definition not to include sufficient conditions because it should also include the equality between the sides as condition".

Almost all the participants considered the statement "The parallelogram is a quadrilateral in which each pair of opposite sides are parallel and equal" an accurate definition of the parallelogram. Eleven of these students wrote that one of the conditions 'equal sides' or 'parallel sides' is enough for a quadrilateral to be a parallelogram. In spite of this knowledge, not any one of them concluded that the definition is not accurate or that it violates the minimalism criterion of definition.

## Deductive geometric reasoning

The third item in the questionnaire was related to Deductive geometric reasoning.

*The mathematics teacher defines "The trapezium is a quadrilateral in which two opposite sides are parallel" and "The Parallelogram is a quadrilateral in which two pairs of opposite sides are parallel". Rami claims that the teacher's definitions mean that the parallelogram is a trapezium, while Sami claims that Rami is wrong. **Which of these claims is right? Explain your response!***

Answering the third item, 56.5% (35) of the participants supported the claim of Rami that the parallelogram is a trapezium according to the teacher definition, and also supported the opposite claim of Sami that parallelogram is not a trapezium according to the right definition of the trapezium.

19.5% (12) of the participants argue that Rami's claim that parallelogram is trapezium is wrong while Sami's claim that the parallelogram is a not trapezium is right. They argued that the teacher defined the trapezium as having one pair of parallel opposite sides, but she have to define it as having only one pair of parallel opposite sides and the parallelogram have two pairs of parallel opposite sides. This argument also led them to consider only the second claim is right.

24% (15) of the participants wrote that Rami's claim is right while Sami's is wrong. Doing so, they argued that the claim "The parallelogram is a trapezium" is right because the teacher defined the trapezium as having one pair of opposite angles, while she defined the parallelogram to have two pairs of parallel opposite sides. The shape that has two pairs of parallel opposite sides satisfies the condition of having a pair of parallel opposite sides. This means that according to the teacher, the parallelogram is a trapezium.

## Discussion and conclusions

The present research intended to investigate the features of middle school teachers' conceptions of geometric definitions. It could be argued according the research results that the participating teachers have difficulties regarding the understanding the structure of the geometrical definitions and their functions and meaning.

One feature of the participating teachers' conceptions of mathematical definitions is its relatedness to their understanding the sufficient conditions issue of the definition. Some of them did not accept the statement "The parallelogram is a quadrilateral in which each pair of opposite sides are parallel" as an accurate definition of the parallelogram, this statement sufficient in order to deduce the rest of concept attributes. These conceptions of the sufficient conditions also led them to demand non-minimal definitions to be the accurate definitions. This feature agrees with other reports about teachers' conceptions of the definition this result is in agreement with the results from Leikin and Winicki-Landman (2000) and from Zazkis and Leikin (2008) where prospective secondary mathematics teachers indicated a preference for the barely-not-minimal definition over a minimal definition.

A second feature of the participating teachers' conceptions of mathematical definitions is that they differentiate between a definition and a property. They did not accept the statements that describe the parallelogram in terms of its angles or diagonals as definition, saying that it is property and not a

definition, although that these statements satisfy all the imperative features of mathematical definition (Zaslavsky & Shir, 2005). This misunderstanding of the relationship between a definition and a property leads to difficulty in understanding the equivalence between definitions. From these participants' perspective of mathematical or geometrical concepts, for every concept there is only one definition (Leikin & Winicky-Landman, 2001). The participating teachers were not aware of the logical necessities of equivalence (van Dormolen & Zaslavsky, 2003).

Third feature of the participating students' conceptions of mathematical definitions is that it takes into consideration the name of the geometric concept. Some of the students only accepted a definition of the parallelogram that included the term 'parallel' or at least sides, and did not accept a definition that is related to relations between its angles or diagonals. Thus, the name affected the participating teachers' acceptance of some statements as definitions and their rejection of other statements as thus. This result confirms the finding of Haj-Yahya, Hershkowitz & Deryfus (2014) who reported that the parallelogram name affects students' proving processes. It seems that this influence of the name on the participating students' conceptions of definitions hindered these students from considering some of the equivalence and alternative definitions of the parallelogram as accurate definitions.

The fourth feature of the participating students' conceptions of mathematical definitions is that it could include contradictions. More than half of the participating students accepted two statements that result in the trapezium being a parallelogram, as well as the opposite, which means that there is no difference between the shapes. The results from the third class of questions was about the deductive reasoning, the results shows that in many cases the students did not rely their reasoning on the concept definition, this confirm previous results of Edward & Ward (2004) about non-geometrical context.

To conclude, the present research examines mathematics teachers' conceptions of geometric definitions. We found that generally, the participating teachers do not possess the geometric conceptions at the van Hiele fourth level didn't understand what are the imperative features of mathematical definition (Zaslavsky & Shir, 2005). The research results directs the preparation of workshops for teachers, so it would be possible to target in these workshops the features of teachers' conceptions of definitions. These workshops would constitute a platform for discussing the impact of mathematics teachers' conceptions of definitions on their teaching. This would make these conceptions sounder and help these teachers take better decisions regarding how to teach definitions in the mathematics classroom. Research is needed here to verify the consequences of educational programs on teachers' conceptions of definitions in particular and on their teaching in general. In addition, future research can utilize theoretical frameworks as those suggested Fujita and colleagues (see for example Fujita (2008)), which will clarify other aspects of in-service teachers' conceptions regarding definitions.

# Children's use of spatial skills in solving two map-reading tasks in real space

Cathleen Heil

Leuphana University Lüneburg, Germany; cathleen.heil@leuphana.de

*Map reading is a cognitively demanding spatio-geometric activity for children that involve understanding and updating person-space-map relations during movement in a large environment. Drawing from the psychological literature, children's skills in reasoning about those relations were tested in two tasks of a map-based treasure hunt on the campus (self-location and place finding), and compared them to their performances in a set of spatial tasks in paper and pencil format. 9- to 12-year old children (N=240) placed colored stickers and arrows on the map to describe their location and orientation at three different places, and laid down three disks to mark locations they identified. Hierarchical linear regression analysis revealed that performances in a set of written spatial tasks predicted up to one quarter of the variance in performances in both map-reading tasks, while sex and strategy choice were not found to be important predictors.*

*Keywords: Geometry education, map tasks, spatio-geometric reasoning, spatial skills.*

## Introduction

Geometry education at primary school is often based on Freudenthal's idea of "grasping space" (1973), and thus aims to contribute to children's thoughtful interaction with the three-dimensional space in which they live, play, and move. Ideally, this goal is achieved at school with a range of spatio-geometric tasks that allow children to complete realistic geometric activities that are similar to their own everyday experience (Lowrie & Logan, 2007).

Within TWG4 of CERME, spatial reasoning and spatial skills have been identified as latent underlying cognitive skills that allow children to develop and apply the four core competencies (reasoning, figural, operational and visual) for geometrical thinking (Maschietto et al., 2013). Although their importance has been emphasized in a range of studies, their role in realistic spatio-geometric activities is little understood (Houdement, 2017). A review of the literature revealed that all studies on these activities in the working group are typically located in a space that is very close to the subject, like for example a sheet of paper, a set of small objects, or a computer screen (Houdement, 2017). In contrast, investigating activities that are located in larger, realistic interaction spaces such as map reading in real space would be closer to the original demand for realistic geometric activities that allow children to "grasp space."

Addressing this gap in the literature and extending the literature on spatial-geometric reasoning of primary children, this study presents two map-reading activities (self-location and place finding) as examples of spatio-geometric tasks that can be completed in larger spaces. By doing so, it seeks to empirically investigate the relative importance of spatial skills, sex, and strategy choice in these contexts.

## Map reading, person-space-map relations and spatial skills

Maps are symbolic representations of the reference environment that allow to mediate between the immediate perception of space and the cognized inference about it, for instance during navigation with a map (Downs, 1981). Maps have been emphasized to foster spatio-geometric thinking in realistic contexts that require the integration of information from the real space that surrounds the learner rather than being based on material that can be perceived from one single vantage point (e.g. Liben & Downs, 1993). Maps provide therefore an important tool for completing spatio-geometric activities in large interaction spaces, which, in turn, requires cognitive processes (Montello, 1993) and spatial knowledge (Brousseau, 2000) that are different from processes and knowledge used to solve paper- and pencil spatial tasks.

To read a map, in particular to establish a relationship between the real physical environment and its abstract-geometric depiction, is a complex task that requires not only spatio-geometric skills, but also requires the understanding of basic mathematical concepts. Following a rather descriptive argumentation of Muir and Frazee (1986), eight skills relate to map reading: (1) interpreting symbols, (2) understanding scale, (3) calculating distances, (4) understanding perspective, (5) finding locations, (6) determining directions, (7) identifying elevation, and (8) imagining relief. Among those skills, three explicitly relate to spatio-geometrical ones ((4) – (6)). Although map reading can be considered being a complex activity that involves all eight skills in an interrelated way, the focus of this paper is on the skills of understanding perspective, finding locations and determining directions in this study, and approach and conceptualize them further from a psychological perspective.

Two typical tasks of map use that require all three skills outlined above, are direct navigation towards a certain goal (*place finding*) and understanding where you are on a map (*self-location*). Self-location is a prerequisite of further map use and requires linking their current location in the environment to the analogue location on the map. Hereby, locating themselves on a map does not only involve identifying their position on the map, but also considering their current orientation. Following Liben & Downs (1993), to do so, children must understand three different relations between themselves (person), the environment (space) and the representation of the environment (map). These three relations are perception and reflecting on the own location in space (*person-space* relation), understanding and establishing links between the space and its representation (*space-map* relation) and understanding their own location on the map (*person-map* relation).

Children acquire the knowledge to master the person-space relation relatively early in their development due to their sensorimotor exploration of space. That is, children demonstrate relatively early that they are for instance intuitively able to identify their home location or the location of other landmarks. However, adjusting this intuitive person-space understanding by taking information on the environment from a map, thus establishing geometrical correspondences between the environment and its depiction in a map, appears to be achieved much later in the children's development (see Liben & Downs, 1993, for references in the developmental literature).

In particular, understanding geometric correspondences comes to reason about the space-map relation by identifying whether the map aligns correctly with the environment and further involves projective reasoning for establishing the person-map relation. Whenever the map is not aligned with the

environment, children need to engage some form of cognitive compensation. Understanding the person-space-map relation then becomes an intertwined cognitively challenging process of mentally rotating the map to align it with the environment (thus establishing the space-map relation) and imagining the own locating and heading on a map (thus establishing the person-map relation).

Spatial cognition psychologists have modeled the skills to establish and maintain the correct person-space-map relations during navigation by relating them to the concept of spatial skills (e.g. Liben & Downs, 1993, Liben et al., 2013). Spatial skills is an umbrella term that refers to a set of cognitive skills that allow an individual to encode, maintain, and transform a spatio-visual stimulus to induce a certain inference or a spatial behavior. From this perspective, aligning a map with the environment has been modeled as mental rotation skill (e.g. Shepard & Hurwitz, 1984) and imagination of the own position on a map as perspective taking skill (e.g. Liben & Downs, 1993).

While the literature on spatial cognition proposed this relation at the level of latent cognitive processes, it is not clear whether this relation holds true from the perspective of individual differences. The goal of the study was therefore to empirically test whether and to and which extent individual differences in tasks requiring spatial skills are important predictors for individual differences in map-use tasks. It was also tested, whether sex (e.g. Voyer & Voyer, 1995) and spontaneous strategy use (e.g. Liben et al., 2013) were also important predictors.

## **Methods**

### **Research design**

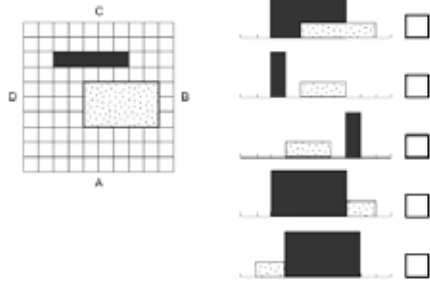

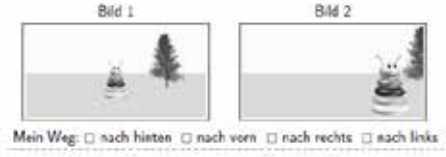

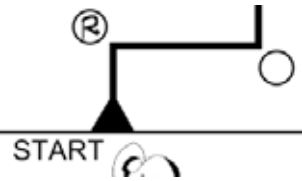

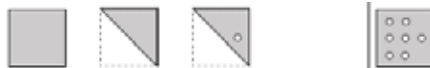

This study used a quantitative design that was based on two psychometric tests: First, a paper-and-pencil test that measured performances in a set of spatial tasks that required the use of spatial skills. Second, a map-based orientation test that measured performances in self-location and place finding tasks that required the skills to constantly update person-space-map relations. Scores in the tests were interpreted as indicators of individual skill and related to each other in multiple regression models.

### **Participants**

The sample consisted of 240 primary school children (111 boys, 129 girls) out of a town in Northern Germany. The children were aged between 9 and 12 years (mean age 9.17,  $SD=.50$ ) and formed a heterogeneous sample in terms of scholar achievement and social background. The sample was not specifically chosen, but consisted of all children in the town that got the permission to participate in the study.

### **Paper and pencil tasks**

The children completed a set of different paper and pencil tasks in 45 minutes. The test consisted of eight different tasks (see Table 1 for examples of tasks), four of them being adoptions of adult tasks (e.g., a 2D mental rotation tasks based on Ekstrom's Card Rotation Test, a 3D mental rotation task similar to the Vandenberg's Mental Rotation Test, a Paper Folding Task analogue to Thurstone's Punched Holes Test, and a perspective taking task analogue to the Guilford-Zimmermann boat test). The four other tasks were developed from the scratch and tested within a pilot study with  $N=222$  children. Those tasks required for example perspective taking processes in labyrinths.

Task	Description and Scoring	Example item
Boxes	Requires sorting the corresponding side views of an array of boxes that is presented in plan view. The children need to sort all four side views out of five possible solutions. 3 items with polytomous scoring (2-1-0).	
MEADOW	Requires determining directions (forward/backward & left/right) of mental movement that explains a shift from picture one to picture two. 6 items with dichotomous scoring.	
LR	Requires imagining going along a path on a map and to decide on each crossing whether to turn left or right. 4 items with dichotomous scoring.	
PFT	Adoption of the Paper Folding Task. 6 items with dichotomous scoring.	

**Table 1: Four tasks of the paper and pencil test.**

### Map-based orientation tasks

The field area was the campus of Leuphana University has a mostly symmetrical of buildings that are connected via perpendicular roads (see Figure 1). On the campus, the experimenter installed a yellow, a blue and a red flag. The children were individually given a map of the campus as well as a set of six stickers, three of them for indicating locations (points of 5mm diameter), and three of them for indicating directions (little arrow stickers). They further obtained a set of three numbered disks. After some preliminary tasks on map understanding, the children completed two map- tasks. During the tasks, they were forbidden to turn the map.

**Figure 1: Flags and discs on the campus**

1. *Self-location*: The children followed the experimenter to each of the flags and were asked to place the location and direction sticker. Wrong answers were corrected for maintaining equal change for every tasks after putting each sticker.
2. *Place Finding*: At the red flag, the children were told to find numbers on the map and place the corresponding disks at the right location on the campus. The experimenter recorded the locations

where each of the three disks were placed. Whenever a disk was misplaced, the children were corrected afterwards, thus maintaining equal chance for the subsequent disk.

These tasks required the children constantly update the space-map relation since they were not allowed to turn the map. Moreover, solving the tasks required to track where they are on the map, thus updating the person-map relation while integrating visuospatial information from the environment and update their person-space relation.

During the tasks, the experimenter recoded visible strategies such as *tracing* (follow the route with a finger on the map), *matching* (talking aloud about correspondences between map and buildings), *north-orientation* (child orients towards north all the time while walking with the experimenter) and *other* (speaking aloud of left-right changes, gesture, ...).

### Data treatment

The X and Y coordinates of each sticker were encoded. Stickers were scored polytomously with a tolerance of 5mm and 7mm radius of the correct position, giving up to 2 points per sticker, and the direction stickers dichotomously. The locations of the discs were scored with up to two points per disk. In a subsequent step, the data was analyzed using listwise deletion for missing values that occurred during data collection in the map-based tasks.

## Results

### Descriptive statistics

To understand performances of the sample in both tasks, descriptive statistics for the tasks self-location and place location were computed. A descriptive analysis of the two tasks revealed that children performed below the expectation value for the self-location tasks (range=[0,8], M=3.11, SD=2.25, N=231) and about the expectation value in place finding tasks (range=[0,5], M=2.87, SD=1.77, N=207). These results indicate, that self-location tasks remain very difficult to master for children within the sample. In particular marking the correct positions (range=[0,5], M=1.43, SD=1.55) rather than understanding orientation (range=[0,3], M=1.67, SD=0.99) was difficult.

### Hierarchical multiple regressions

*Self-location performance in relation to individual variables.* In a preliminary step, multiple regression analysis was used to test which of the eight spatial tasks that were solved in the test significantly contributed to explain variance in self-location performances. The results indicated that all eight predictors

	Step 1		Step 2		Step 3	
$R^2(p)$	.214 (.000)		.215 (.000)		.233 (.000)	
$\Delta R^2(p)$	.214 (.000)		.001 (.548)		.017 (.289)	
Predictor	$\beta$	$p$	$\beta$	$p$	$\beta$	$p$
LR	.21	.002	.21	.002	<b>.22</b>	<b>.001</b>
PFT	<b>.22</b>	<b>.002</b>	<b>.22</b>	<b>.002</b>	.20	.005
MEADOW	.18	.007	.17	.009	.18	.008
Sex			.04	.548	.01	.832
Tracing					.03	.648
Matching					-.07	.260
North					.11	.065
Other					-.02	.746

**Table 2: Hierarchical linear regression analysis predicting self-location performances (N=230)**

explained 23.0% of the variance ( $R^2=.23$ ,  $F(8,222)=8.38$ ,  $p<0.001$ ). Three of these tasks, LR ( $\beta =.17$ ,  $p=.016$ ), PFT ( $\beta =.14$ ,  $p=.086$ ) and MEADOW ( $\beta =.14$ ,  $p=.048$ ), were found to predict self-location performances significantly ( $p<0.01$ ), and kept for subsequent analysis. In the hierarchical multiple regression analysis, the spatial scores of these three tasks were added in Step 1, sex in Step 2 and four different strategy scores in Step3 (see Table 2).

As in the preliminary analysis, the three spatial tasks accounted for significant variance in the self-location performances first level of the model,  $F(3,227)=20.61$ ,  $p<0.001$ , with PFT emerging as the most important predictor (see Table 2 for standardized betas and the corresponding probability levels for every step in the model). Prediction was not significantly improved by adding sex in Step 2. The addition of strategies in Step 3 led to a marginal increase of .017 in the amount of explained variance, and revealed walking with orientation towards the north as an almost significant predictor. However, in the overall model comparison, the final model did not differ significantly from the first one which explained 21.4% of the variance.

In summary, the results indicated that individual differences in three spatial tasks only can be seen as significant predictors of self-location performance, predicting a fifth of the variance. Sex and strategy use did not contribute significantly to explain variance.

*Place finding performance in relation to individual variables.* Again, in a preliminary step, multiple regression analysis was used to test which of the eight spatial tasks significantly contributed to explain variance in place finding performances. The results indicated that all eight predictors explained 25.3% of the variance ( $R^2=.25$ ,  $F(8,198)=8.37$ ,  $p<0.001$ ). Three of these tasks, LR ( $\beta =.16$ ,  $p=.024$ ), PFT ( $\beta =.14$ ,  $p=.090$ ) and BOXES ( $\beta =.22$ ,  $p=.009$ ), were found to predict place finding performances significantly ( $p<0.10$ ), and kept for the analysis.

In the hierarchical multiple regression analysis, spatial scores of these three tasks were entered in Step 1, sex in Step 2 and strategy choice in Step 3 (see Table 3). As in the preliminary analysis, the three spatial tasks accounted for significant variance in the first level of the model,  $F(3,203)=21.87$ ,  $p<0.001$ , with BOXES emerging as the most important predictor (see Table 3 for standardized betas and the corresponding probability levels for every step in the model). Again, prediction was not significantly improved by adding Sex in Step 2. The addition of strategies in Step 3 led to a significant increase of .032 in the amount of explained variance, and revealed that ‘other strategies’ to be a significant inhibitor of place-finding performances. The final model was significant,  $F(8,198) = 9.579$ ,  $p<0.001$ , with an  $R^2=.28$ .

	Step 1		Step 2		Step 3	
$R^2(p)$	.244 (.000)		.247 (.000)		.279(.000)	
$\Delta R^2(p)$	.244 (.000)		.003 (.372)		.032 (.072)	
Predictor	$\beta$	$p$	$\beta$	$p$	$\beta$	$p$
LR	.17	.015	.17	.015	.21	.003
PFT	.18	.017	.17	.022	.18	.017
BOXES	<b>.27</b>	<b>.000</b>	<b>.26</b>	<b>.001</b>	<b>.27</b>	<b>.000</b>
Sex			.06	.372	.06	.310
Tracing					-.06	.321
Matching					-.01	.906
North					-.01	.822
Other					-.17	.009

**Table 3: Hierarchical linear regression analysis predicting place finding performances (N=205)**

In summary, the results indicated that individual differences in three spatial tasks emerged as significant predictors of place finding performance, predicting a quart of the overall variance. Sex did not contribute significantly in the prediction. Strategy use led to an overall predicted variance of 28%, but revealed a less well defined strategy group as inhibitor.

## Discussion

This study aimed at investigating children's performances in two map-reading tasks in real space and investigated their prediction by a set of spatial skills and the two other individual variables sex and strategy choice. As anticipated by labelling the proposed activity as a "complex" one, the results indicated that both, self-location and place finding remain challenging tasks for children by the end of primary school. Moreover, a hierarchical regression analysis showed that individual differences in written spatial tasks accounted for up to 25% of the variance in both map-based tasks. I sex nor strategy use were found to be significant predictors in both tasks.

Regression analyses revealed a set of four spatial tasks that predicted the outdoor tasks: LR and PFT were found to be predictors in both outdoor tasks, MEADOW and BOXES for self-location and place finding, respectively. An analysis of these tasks (see e.g. Linn & Petersen, 1985, for the PFT) reveals that they rely on multistep solution processes, in particular require a multistep manipulation of mental images that need to be updated correctly. Tasks that require singular 2D and 3D mental rotations were not found to be predictors. Similarly, perspective taking tasks that are bound to a very particular spatial setting (labyrinth-tasks) were not found to be predictors either. A tentative interpretation of this outcome for educational settings might be that spatial tasks that are interesting for application in real space should fulfill two criteria: first, they should be sufficiently complex, and second, they should not be presented in too particular contexts but rather in general-abstract contexts.

Since we drew on the literature concerning sex-differences in favor of boys in written spatial tasks, we expected to find sex an important predictor in the map-reading tasks in real space as well. In contrast to the literature (Liben et al., 2013), we did not find a male advantage at all. Although we recommend follow-up analyses including interaction terms into the models outlined above, there is an interpretative suggestion that activities with maps in the real space are equally cognitively accessible for boys and girls.

Contrary to other empirical findings (Liben et al., 2013), visible solution strategies did not predict performances in the map-based tasks. One possible explanation is that experimenters just observed the strategies, but the children were not explicitly interviewed. Furthermore, experimenters were not sufficiently sensitized to observe strategies. The documentation of strategies was therefore dependent on the different experimenters that might have documented them in a non-coherent manner. Further studies that focus on strategy use are important.

For a better understanding of the role of spatial skills in realistic spatio-geometric activities from a conceptual point of view, studies should conceptualize and analyze those skills in latent models, thus referring to classes of spatial tasks that share the same cognitive processes and to analyze their relation to the map tasks. This would allow researchers to make more generalized conclusions than it is the case in an analysis based on single spatial tasks.

## Conclusion

By empirically testing psychological assumptions, this paper demonstrates that spatial skills are an important underlying cognitive skill in realistic geometric activities that allow children to understand the real space they interact with in their everyday life. Investigating spatial skills and their underlying cognitive processes, but also spatio-geometric activities in larger interaction spaces remain therefore important challenges for conceptual work and discussions in TWG4.

## A step in the development of an evidence based learning progression for geometric reasoning: focus on shape and angle

Marj Horne and Rebecca Seah

RMIT University; [marj.horne@rmit.edu.au](mailto:marj.horne@rmit.edu.au)

RMIT University; [rebecca.seah@rmit.edu.au](mailto:rebecca.seah@rmit.edu.au)

*The Reframing Mathematical Futures II Project set out to develop an evidence-based learning progression for mathematical reasoning in years 7-10 of schooling. This paper reports part of the process and findings particularly around student reasoning about shape and angle as part of the development of a progression for geometrical reasoning. Concerns are raised about the low level of understanding and reasoning in these areas and the need for further research in the study of the development of the concept of angle.*

*Keywords: Geometry, measurement, learning progression.*

### Introduction.

Geometry and spatial visualization is important for STEM (Wai, Lubinski & Benbow, 2009) and the development of number understanding (Verdine, Golinkoff, Hirsh-Pasek, & Newcombe, 2017). Yet in some countries the amount of geometry being taught has been reduced over many decades leading to a decline in teacher knowledge. The improvement of the teaching and learning of geometry requires both attention to the curriculum and enabling teachers to implement the curriculum more effectively.

The Australian Mathematics and Science Partnership Program (AMSPP) funded by the Australian Government Department of Industry, Innovation, Climate Change, Science, Research and Tertiary Education, was established essentially to increase the participation and expertise in STEM related areas. The Reframing Mathematical Futures Project II (RMFP2), as part of the AMSPP aimed to build a sustainable, evidence-based learning and teaching resource to support the development of mathematical reasoning in Years 7 to 10. This paper reports on part of this process with a particular focus on students' reasoning about shape and angle size.

Learning progressions, while not new, relatively recently have become the focus of systematic research efforts (see Siemon et al. 2017). There have been different interpretations of the meaning and use of learning progressions (and the closely related learning trajectories - see the special edition of *Mathematics Teaching and Learning*, 6(2), 2004). The learning progression, as we are using the term, describes stages in the development of geometric reasoning which are evident sequentially in the responses of many students. It assumes that learning takes place over time, and that teaching involves recognising where learners are in their learning journey and providing challenging but achievable learning experiences that support learners' progress to the next step in their particular journey (see Siemon et al., 2017 for recent research and development on this). The learning progression is thus closely linked with teaching and learning. The research presented in this paper is in the context of a larger study which is developing a learning progression for geometric reasoning.

Geometric reasoning is the ability to critically analyse axiomatic properties, formulate logical arguments, identify new relationships and prove propositions. It is demonstrated in early stages

through attention and explanation with students then moving to describing, analysing, inferring, conjecturing and deducing geometric relationships leading to them engaging in formal proof (Brown, Jones, Taylor, & Hirst, 2004). Being able to invent and apply formal conceptual systems to investigate geometric relationships is part and parcel of reasoning geometrically (Battista, 2007).

In common with other developed learning progressions and trajectories a synthesis of relevant research literature was undertaken to establish a hypothetical learning progression for geometric reasoning which included a breadth of geometric concepts from the curriculum since its application was to be with classroom teachers. In constructing the progression, we acknowledge that the dominance of van Hiele levels on geometric thinking research, and their neglect of visualisation, meant that the framework we developed needed to move beyond these factors and recognise that students can reason at multiple levels, at different rates for different concepts. Our synthesis of available research findings led to the development of an initial hypothetical geometric learning progression that included both geometry and measurement concepts and which was based on Battista's (2007) proposed four levels of thinking: visual-holistic reasoning, analytic-componential reasoning, relational-inferential property-based reasoning, and formal deductive proof. He expanded the development of property-based thinking to progress from visual-informal, to informal insufficient-formal reasoning and finally sufficient formal property-based reasoning. The hypothetical learning progression we proposed (Seah & Horne, 2019) made a distinction between descriptive reasoning - using informal language to explain what one sees and analytic reasoning - using formal language to analyze properties of shapes. It also encompassed concepts from a range of aspects of geometry including shape, transformation and location, and measurement. This allowed us to better investigate the growth in the connectedness between visualization and mathematical discourse and contributed to the design of instructions that targeted specific thinking within a framework which was connected to, but not defined by curriculum.

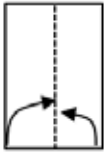

The research question considered in this paper is how do students' reason about angle, angle measure in a two dimensional context of shape. This is set in the overarching project of developing a learning progression for geometric reasoning.

## Method

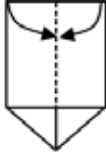

Based on the hypothetical learning progression we designed a series of pen and paper assessment tasks, which were based on practical situations, and would allow students to demonstrate reasoning as well as other knowledge and skills. While there have been some studies (for example, Keiser, 2004; Mitchelmore & White, 1998), angle and angle measure is an area of geometry that has not received a lot of attention yet occupies considerable curriculum space connecting to many aspects of shape and measurement leading through to trigonometry. Typical angle questions in text books in years 7-10 require students to find the magnitude of angles from diagrams. The intention for these assessments was to seat the problems in real situations to which students could relate. An example of such a task is an angles task shown in figure 1 where students physically construct the angles through paperfolding before finding their magnitudes. The intent of this question was to focus on students' ability to use knowledge of properties of shape to make deductions about angle measure hence part a) focused on the properties of the 2D shape while part b) sought angle measures and explanation.

You will need the shape you made in class. The steps and diagrams below show how you made the shape.

Step 1

Step 2

Step 3

Step 4

Step 5

**Step 1** Fold an A4 paper in half lengthwise to make a crease line in the middle of the page.  
**Step 2** Fold two corners to the middle at the bottom  
**Step 3** Fold two corners to middle at the top  
**Step 4** Fold the new corners on the sides at the bottom to the middle  
**Step 5** Do the same with the top

**a** [GANG1]  
 Phoebe made the same shape that you made using A4 paper.  
 She said her shape is a rhombus.  
 Do you agree? Explain your reasoning.

**b** [GANG2]  
 When Phoebe unfolds the paper she found a number of crease lines.  
 Find the marked angles on the crease lines:  
 Angle  $f$  = \_\_\_\_\_ Angle  $h$  = \_\_\_\_\_ Angle  $s$  = \_\_\_\_\_  
 Explain how you worked out the angles.

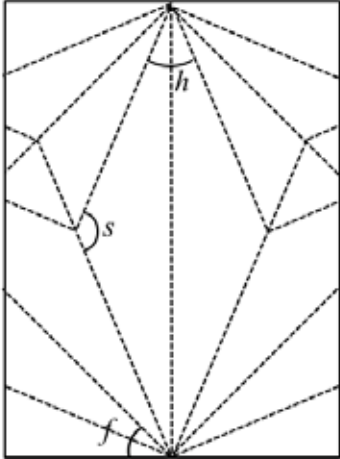

Figure 1: Shape and angles task

Each task was designed with a marking rubric to enable teachers to easily score the students' work. The rubric for the angles task is shown in Table 1. The scoring rubric requires clear reasoning to be given for the responses to attain the higher scores. GANG1.1 refers to a rubric score of 1 on the question GANG1 and is used in later analysis.

SCORE	DESCRIPTION For GANG1
0	No response or irrelevant response
1	Disagree it is a rhombus based on appearance rather than properties
2	Disagree it is a rhombus but claim it is a parallelogram or some other quadrilateral such as kite with some properties specified, <b>or</b> Agree it is a rhombus with reason relying on appearance such as "if you turn it to rest on its edge it is a rhombus".
3	Agree it is rhombus specifying two properties correctly but insufficient / incorrect properties to define it.
4	Agree it is rhombus. Explanation needs to include necessary and sufficient properties, that is, it has 4 equal sides, <b>or</b> is a parallelogram with one of the following properties <ul style="list-style-type: none"> <li>• Adjacent sides equal</li> </ul>

	<ul style="list-style-type: none"> <li>• Diagonals bisect each other at right angles or diagonals bisect the angles</li> <li>• Two lines of symmetry</li> </ul>
<b>SCORE</b>	<b>DESCRIPTION For GANG2</b>
<b>0</b>	No response or irrelevant response
<b>1</b>	Incorrect angles
<b>2</b>	At least 2 angles correct but no reason given or one angle correct with correct reasoning
<b>3</b>	Two angles found correctly with sensible reasons or all angles correct with insufficient reasoning
<b>4</b>	All angles correct with clear reasons given relating to the folding and properties. $F = 45^\circ$ ; $h = 45^\circ$ ; $s = 135^\circ$ (e.g., <i>Folding corner to centre creates half right angle; All angles around centre of side equal so any 2 make <math>45^\circ</math> or Four angles of quadrilateral add to <math>360^\circ</math></i> )

**Table 1: Rubrics for shape and angle question**

A number of assessment forms, each with 6-7 questions, were structured covering a range of geometric content and trialled with students in years 7-10 in order to collect data on the questions and refine them as needed. On the basis of these trials and the student responses assessment forms were finalised and data collected first from a small group of trial schools in three different states and then from the larger group of project schools across Australia. This data was analysed at two levels. The first was at the level of individual questions focusing on the reasoning about specific geometric and measurement constructs while the second was at a meta-level using item response theory (IRT). For a detailed description of this IRT analysis see Siemon and Callingham (2019). The analysis led to the identification of eight zones based on the evidence of what these students could do. From this a learning progression based on the descriptions of these zones was created.

## Results and Discussion

The teachers in all the schools had a choice of which assessment forms their students would complete. Many chose not to assess geometry. The data presented here is from 279 students in years 7-10. Table 2 shows the percentage of students attaining each rubric score for the two questions.

Rubric score	Shape (GANG1)	Angle (GANG2)
0	39	50
1	7	25
2	4	8
3	43	9
4	7	8

**Table 2: Percentage of students in years 7-10 attaining rubric score**

As can be seen many students did not attempt the question or gave irrelevant answers. The following section shows the types of responses to the two questions.

### Reasoning about shape

A sample of student responses are shown here in table 3. Orientation was an issue for some students with confusion about diamond and rhombus for many students, like S2, thinking it was only a rhombus when it was positioned with a horizontal edge.

Score		Reasoning
1	S1	I don't agree the shape wasn't wide enough to become a rhombus. It is a diamond.
2	S2	Yes because if you turn it on its side it is a rhombus
2	S3	Yes because its [sic] just a square pushed over which is a rhombus (picture shown of square and 2 pushed over rhombuses)
2	S4	No it's a parallelogram. It has two pairs of parrallel [sic] lines and 2 pairs of angles
2	S5	I agree because to [two] of the opposite sides were equal
3	S6	Yes I agree a rhombus 2 horizontal parallel lines 2 diagonal parallel lines
3	S7	Phoebe is correct when she states that the shape made from the paper is a rhombus as the opposite sides are equal to one another, opposite angles are equal to each other and the sides are parallel
3	S8	This shape is a rhombus because properties of a rhombus all sides are equal, diagonals bisect each other at right angles, all angles are equal
4	S9	I agree. This is because all the sides are the same length. There are also two pairs of parallel lines There are two acute angles and two obtuse angles.
4	S10	Yes all the sides same measurement

**Table 3: Student reasoning about shape**

The explanations given by students such as S1-3 could be classified as “it looks like ...” with either agreement that it is a rhombus or disagreement because it is a diamond. S3 goes a little further with dynamic imagery showing in the response. S4 and S5 began to use properties in their reasoning though limited and insufficient. S6 and S7 used properties but defined a parallelogram rather than a rhombus with S6 also indicating orientation. While giving a necessary and sufficient property initially, S8 went on to give further properties, the last of which was incorrect. For the highest rubric score S9 also gave extra properties but these were written as an extra while S10 correctly gave just the important property. None of the students specified that the sides had to be straight or that the shape was planar and closed but in the context this was not seen as being necessary.

### Reasoning about angle sizes

Table 4 shows some of the students reasoning about the angle size.

Score		Angles	Reasoning
-------	--	--------	-----------

1	A1	acute acute obtuse	f, h smaller s bigger
1	A2	7 7 6	The angles from s are 6 because there are 6 lines finishing at the s angle. All the angles from the h are 7 because they are also reaching the end. All the angles from the f are also touching the end of the page
1	A3	30 45 20	The way I worked it out was I pictured the protractor [sic] in my head and trying to figure the degrees of it
2	A4	45 45 -	I estimated the angles by imagining a 90 degree angle on the f, s, h
2	A5	45 70 160	[a right angle shown divided in two to make 45] h $180/2 = 90$ $90/2 = 45$ because of the 3 angles make 180 so you can divide by 3
4	A6	45, 45, 135	The half creases indicate two right angles. H and f are halves of the right angles so $90/2=45$ . Quadrilateral has internal sum of 360 h and the opposite is 90 total $S=(360-90)/2$
4	A7	45 45 135	Angle f is based on a straight line and there are 8 equal angles ( $180/8 = 22.5$ ) but f is two of these $22.5 \times 2 = 45^\circ$ Angle h is the same thing just positioned differently Angle s I found because a triangle equals $180^\circ$ $22.5 + 22.5 = 45$ $180-45 = 135$ (with diagram)

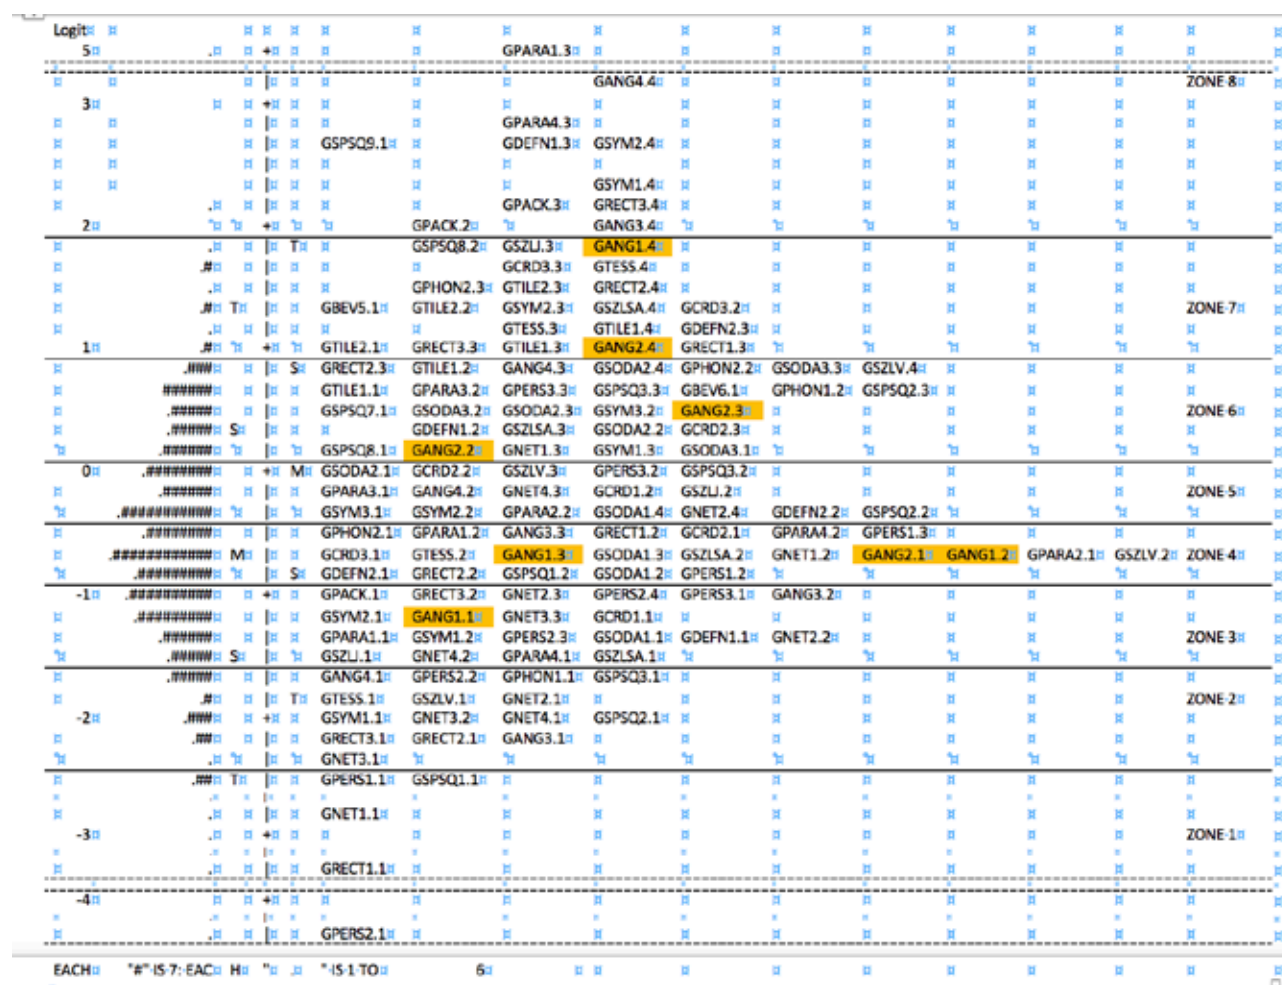

**Table 4: Student reasoning about angle size**

A2 demonstrated a lack of comprehension about the concept of angle using the number of lines meeting at the point to provide the angle size. Many of the students associated angle size with protractors and when asked to find the angles, the only way of which they were sure was to measure using a protractor, or for A3 and A4 imagining one, which suggests that they have had little experience of reasoning about angle sizes from given information and their knowledge of geometry. A5 began with a correct calculation using a diagram to illustrate but then became confused. A6 and A7 both calculated correctly giving reasons. The rubrics and students' responses show increasing sophistication in reasoning. However, there was little evidence of students using relational inferential property based reasoning. While the theoretical framework with which we began was useful in the design of questions and aspects of analysis the final learning progression developed is based on descriptions of what the students actually demonstrated in their geometric reasoning.

Based on responses from many students and the responses to 36 different questions on the assessment forms of which this angles question is only one, an item response analysis was done using Rasch modelling (See Siemon & Callingham, 2019). Figure 2 show the logit map returned by the analysis, based on valid responses from 742 students. The responses to the GANG questions have been highlighted on the map. The dotted horizontal lines show where some blank rows were removed.

From the map of the item responses it can be seen that GANG1, the shape question, has responses spanning zones 3 to 7 and GANG2, the angles question, spans zones 4-7. Based on these responses the descriptions of what students could generally do at each of the zones provided the evidence based learning progression for geometric reasoning. From this question at zone 3 the students were

recognizing shape because it looked like it but were not yet correctly finding any angles. At zone 4 they were starting to reason about shape using properties and were responding to angle size with general information such as acute, obtuse and right angles. In zone 6 they were correctly finding some angles and were able to explain their reasoning about some of these. By zone 7 they were able to identify shape giving necessary and sufficient properties and were able to reason about the magnitude of angles providing sound explanations.

**Figure 3** Logit map of responses to assessment forms

According to the curriculum these students are meant to have studied knowledge about angles in geometry and the properties and identification of quadrilaterals before year 8 so it is of some concern that almost 80% of students were operating below zone 6 with 75% unable to find the magnitude of an angle in this situation. Some students showed they were not even clear about the concept of angle.

## Concluding comments

The students' reasoning about angle and angle measure was generally at a lower level than indicated by the curriculum. Students often did not have the basic knowledge of the properties of quadrilaterals sufficiently connected to enable them to use these in reasoning about angle size. The student responses indicate many issues in their learning about shape and angle and further investigation is

needed, particularly about the understanding of angle and angle measure. The analysis of the student answers to the questions combined with the item response analysis allowed a learning progression based on students' actual responses rather than just a validation of a proposed hypothetical progression. The full learning progression is based on all the questions used in the analysis and not just the one question and while the focus is reasoning, reasoning cannot be separated from the understanding of the underlying concepts. Since the final learning progression developed is based on what students could actually do it should be of use to teachers enabling them to map students' progress and inform teaching. Further research is needed on the implementation of such a progression.

# Task design with DGEs: The case of students' counterexamples

Keith Jones<sup>1</sup> and Kotaro Komatsu<sup>2</sup>

<sup>1</sup>University of Southampton, Southampton Education School, UK; [d.k.jones@soton.ac.uk](mailto:d.k.jones@soton.ac.uk)

<sup>2</sup>Shinshu University, Institute of Education, Japan; [kkomatsu@shinshu-u.ac.jp](mailto:kkomatsu@shinshu-u.ac.jp)

**Keywords:** Task design, dynamic geometry environment, counterexample, proof.

## Introduction

Geometry, being one of the main areas for proof-related activity in school mathematics, is a topic in which learners can work with counterexamples. Sinclair et al. (2016) recently highlighted that more research is needed on task design with dynamic geometry environments (DGEs). We are addressing these issues by elaborating a set of theory-informed task design principles involving DGEs and using these to study students working with geometric diagrams (Jones & Komatsu, 2017; Komatsu & Jones, 2019). Given the importance of networking theoretical approaches, in this short paper we build on our studies by employing a conceptual framework on virtual manipulatives (Osana & Duponsel, 2016). Our research question is how, in using Osana and Duponsel's framework, our task design helps students to produce and address what they think are counterexamples in geometry.

## Virtual manipulatives

Following Moyer-Packenham and Bolyard (2016), DGE tasks where on-screen objects are draggable can be regarded as virtual manipulatives. Osana and Duponsel (2016), based on a thorough review, proposed that task design with virtual manipulatives should take into account: the *surface features of representations*, the *pedagogical support*, and *students' perceptions and interpretations*.

## Method

We undertook a task-based interview (of 35 minutes) with two prospective teachers from a national university in Japan. Each of the participants had experience of using DGEs. They worked on the tasks in Figure 1, which were based on our design principles (for details, see Komatsu & Jones, in press). For data analysis, we used video records of the task-based interview, transcripts of the undergraduates' talk, their written work, and their DGE file.

Task 1. In parallelogram ABCD, draw perpendicular lines AE and CF to diagonal BD from points A and C, respectively. Prove that quadrilateral AECF is a parallelogram.

Task 2. Construct the diagram shown in Task 1 using a DGE. Move the vertices to change the shape of parallelogram ABCD, and examine whether quadrilateral AECF is always a parallelogram.

**Figure 1: Tasks used in the interview**

**Figure 2: Types of diagrams produced by the undergraduates**

The undergraduates completed Task 1 by producing a valid proof where they showed that  $AE = CF$  and  $AE \parallel CF$ . In our analysis, we focus on how the undergraduates worked on Task 2.

## Analysis

The undergraduates produced various diagrams with the DGE, as shown in Figure 2. They considered that the cases shown in Figures 2b and 2d were counterexamples to the statement (quadrilateral AECF is a parallelogram). They successfully addressed the case of Figure 2d by extending the original statement (as in Figure 2e) and proving that quadrilateral AECF in this case is a parallelogram. Here, we summarise how the set of tasks in Figure 1 embody the three elements of the virtual manipulatives framework of Osana and Duponsel (2016):

- Task 1 contains a given diagram. This diagram includes a specific representational feature; namely a ‘hidden’ condition implying that perpendicular lines from points A and C *always* intersect with diagonal BD. By this *surface feature*, and the *pedagogical support* in the text in Task 2 explaining the DGE use (i.e. use of the DGE to check the truth of the statement), the undergraduates could discover what they viewed as ‘counterexamples’ to the statement (as in Figures 2b and 2d).
- *Pedagogical support* included in Task 2 was not excessive in the sense that this task gave the undergraduates the opportunity to explore the task on their own by not specifying what they were expected to do when discovering what they might consider to be ‘counterexamples’.
- The sequence of Task 1 and Task 2, designed by taking *students’ interpretations* of counterexamples into account (see Komatsu & Jones, 2019), stimulated the undergraduates’ subsequent activity where they spontaneously dealt with the case of Figure 2d by extending the original statement with proving in Figure 2e.

## Conclusion

This analysis illustrates how our theory-informed design principles are further supported with the conceptual framework on virtual manipulatives of Osana and Duponsel (2016) in terms of the *surface features of representations*, the *pedagogical support*, and *students’ perceptions and interpretations*.

# The connection between angle measure and the understanding of sine

Valentin Katter

Bielefeld University, Germany; vkatter@math.uni-bielefeld.de

*This paper presents a project in progress that seeks to gain empirical insights into the network of mental representations associated to sine of pre-service mathematics teachers as well as their thinking and typical errors and misunderstandings. First collection of data show that students' concepts of sine vary significantly and that the students have problems associating meaning to the value of sine. It is assumed, that there is a connection between the knowledge of degree and radian measure of angles and the understanding of sine and cosine. Further data will be obtained in a second phase that will include semi standardized interviews. These interviews will also contain aspects of the derivative of sine.*

*Keywords: Trigonometry, sine, angle measure, Radian, Grundvorstellungen.*

## Introduction

In the last few years, little attention has been given to the teaching and learning of Trigonometry in Germany. Most of the work focuses on subject-matter analysis (Korntreff, 2018; Filler, 2009; Malle, 2001). Unfortunately, there is not a lot of empirical research on the students learning process and furthermore, Trigonometry is slowly disappearing from the Curricula of many federal districts due to cutbacks of mathematical contents. This is unfortunate for many students who want to engage in a study of Natural Sciences, Engineering or Mathematics, in which the knowledge and the profound understanding of trigonometric functions are basic requirements for successful academic studies. Therefore, it is important to evaluate the current situation of students who start their careers and to draw a picture of their understanding of Trigonometry, including obstacles that they are confronted with. Major issues in the learning process of Trigonometry are the transition from right triangles to the coordinate plane, the understanding and use of radian measure and the modelling of periodic processes with trigonometric functions.

Since Trigonometry is an essential component of the high school curriculum throughout the United States and other countries, there is some international research on the learning and teaching of Trigonometry. There has been some research regarding students learning of Trigonometry with a focus “on the move from right triangle Trigonometry to rotations about the origin, then to the unit circle, and finally to the sinusoid” (Brown, 2005, p.85). In Brown’s study, preliminary interviews suggest the classification of three different ways students think about sine and cosine in the beginning of the learning process, that seem to correlate with their general geometric and algebraic abilities. Students interpreted values of sine and cosine as 1) ratios in right triangles, 2) distances from the axes, and/or 3) coordinates of a point. These different approaches could be traced back to their use of words and to what they wrote down in their solutions of given exercises.

Due to the changes in the school Curriculum and the importance of Trigonometry in many fields of study, it is crucial to know what previous knowledge about Trigonometry students bring to their

academic carrier at the university. Beyond that it is of great interest to know which mental representations were developed by the students and how these Representations interact with each other. When talking about mental Representations I'm referring to the concept of *Grundvorstellungen*<sup>1</sup> which will be explained further in this paper. These GV prepare the ground for reasonable solving of problems in Trigonometry. The Theoretical Framework of this paper aims to

1. give an Overview over the complex different GV of sine,
2. show the interconnection of different GV of sine, especially the transition from right-angled-triangles to the Unit Circle.
3. present some of the previous mathematical content that these GV are built on, in particular the measurement of angles,

The planned research that is presented in this paper intends to verify whether these Interconnections and Dependencies between GV really exist in the students minds. In this case, the GV of sine can be a useful tool to diagnose learning problems in the field of Trigonometry.

## Theoretical Framework

### *Grundvorstellungen of sine*

Apart from the mathematical content that is analyzed in this study, an important didactical question is: What do students (literally) think when dealing with sine and cosine? There are different theories that strive to give a good explanation for the construction of mental representations of mathematical objects using for example the theory of *concept image* and *concept definition* (Tall, D., & Vinner, S. 1981). In German literature, a related theory uses the Terminology of *Grundvorstellungen* (vom Hofe & Blum, 2016). GV present a didactical concept that classify mental mathematical representations.

GVs thus describe relationships between mathematical structures, individual psychological processes, and subject-related contexts, or, in short: the relationships between mathematics, the individual, and reality. (vom Hofe & Blum, 2016, p.231)

The work with GV has a long tradition in the area of didactics of mathematics in Germany and has been developed in various branches of mathematics like basic arithmetics, geometry, algebra, functions etc. Yet, little work has been dedicated to the concept of GV in the area of Trigonometry. A first attempt to categorize these GV of sine on a normative level can be found in the paper of Salle and Frohn (2017). They distinguish four GV of sine and cosine:

1. Proportion – GV  
This GV is based on the idea of the sine as the ratio of two sides in a right angled triangle. The value of the sine corresponds to a quotient.
2. Projection – GV  
The value of  $\sin(\alpha)$  can be interpreted as reduction factor  $b = \sin(\alpha) \cdot a$ . One can think of a shadow that is casted by orthogonal light rays.
3. Unit-Circle – GV

---

<sup>1</sup> further abbreviated as GV

The Unit-Circle – GV is associated with the parametrization of the Unit-circle, specifically the circular motion of an object. The value of the sine corresponds to a number which provides information about the position of an object.

#### 4. Oscillation – GV

The mathematical modelling of periodic processes requires the Oscillation – GV. To give a mathematical model of a vibrating string via the sine function, the Oscillation GV is needed.

Apart from this study, there has not been any empirical research regarding the GV students might develop over the course of a learning cycle yet. The first collection of data of the present study indicates that the GV of sine of pre-service mathematics teachers vary significantly. When asked what sine means to them, they mention sinusoids, right-angled triangles, angles, the theorem of Pythagoras and the Unit Circle.

At this point I want to emphasize two important aspects. First of all the GV of sine are quite complex, that is why I will introduce the distinction between primary and secondary GV. Regarding that distinction primary GV need to constitute a relation to real world phenomena whereas secondary GV relate to “imagined actions dealing with mathematical objects and means of representing these objects, such as number lines, terms, and function graphs” (vom Hofe & Blum, 2016, p. 234). Secondary GV therefore can depend on the understanding or the mental representation of other mathematical objects. To give an example: A sustainable GV of sine can rely on the concept of an angle, or on the concept of a function. Secondly it is important to note, that GV form a network. That is they are connected and influence each other, “GVs are not regarded as isolated fixed entities, but as variable parts of a growing and changing system” (vom Hofe & Blum, 2016, p. 229). This influence exists between different mathematical objects as well as between different GV of on mathematical object.

### **Interconnection of GV - From right-angled triangles to the unit circle**

The Interconnection between the different GV of one mathematical object can be seen very clearly in the case of the Proportion-GV and the Triangle-GV. The learning of Trigonometry usually takes place in two learning cycles. In the German curriculum sine and cosine are introduced as the ratios of sides in a right-angled triangle in classes 8 or 9. In this part of the learning process sine takes angles of triangles as an input that are measured in degrees. The most common exercises consist of finding the unknown side of a triangle. At this point sine and cosine can be seen as rather stiff tools that only serve a specific purpose. On this topic, Thompson comments as follows,

In students’ understanding sine, cosine, and tangent do not take angle measures as their arguments. Rather they take triangles as their arguments. [...] Also, angles do not vary in triangle Trigonometry. (Thompson, 2008, p.3)

In class 10 the sine receives new meaning when it is introduced via the unit circle. In this part of the learning process sine takes angles as an input that are measured in radian and is introduced as a periodic function. This transition from the rather stiff representation of sine on right angled triangles to the dynamic representation on the unit circle presents many obstacles to students of Trigonometry. Brown (2005, p.222) found that students have problems understanding the role of the unit in the unit circle and finding rotation angles in standard position in the Cartesian plane. Another finding showed

that more than a quarter of the 119 participants of Brown's study were not able to make the move from the unit circle to the sinusoid and couldn't even explain what was represented on the  $x$ - and  $y$ -axis of the sinusoid.

Figure 1. Transition from right-angled triangles to the unit circle

Students struggle with the dual nature of sine as a ratio or a number (Brown 2005). Depending on what resources students have to think about angles, this struggle might be associated with the lack of knowledge and understanding of radian measure.

### Building on previous GV - Radian and degree measure

As mentioned earlier in this paper the GV of sine build on previous known mathematical objects, in particular students need to have a concept of angles and angle measure. The understanding of radian and degree measure concerns multiple mathematical aspects. One aspect is certainly about the measuring process itself, besides the way we measure angles is deeply connected with the way we think about angles. What is an angle? What is a measure? How is a unit defined and for what reasons? Concerning the question “what is an angle?” According to Jordan (2006) there are at least three different aspects of understanding related to angles: the notion of rays, the notion of a field and the notion of a rotation. A more thorough investigation of the interpretation of the angle concept can be found in the work of Mitchelmore and White (1998). They argue that the learning process of the angle concept develops in three stages. First, students have a situated angle concept, in the second stage the students develop a contextual angle concept and in the third stage they are able to build an abstract angle concept.

When thinking about angles in 360 degrees, one possible way to interpret 1 degree is to think of it as a piece of a circle, but there are also other ways to think about angles.

Instead of thinking about a circle that is cut into pieces it is also possible to imagine parts of a rotation or the arc

Figure 2. the arc of two circles measured in radian

of a circle. In this sense, a degree is just a tiny part of a movement. For example, the distance a gondola of a ferris wheel has moved within a certain time. If we start thinking about angles in this way, there are also different plausible ways to define the angle measure. It is possible to define the angle measure as the length of an arc of a circular motion. This is when the idea of the radian measure

emerges. To keep the measurement independent of the size of the circle the unit is defined by the radius of the circle and a given arc is measured in relation to this radius.

The way angles are measured is one of the most significant differences between right-angled triangle Trigonometry and Unit Circle Trigonometry. Accordingly, the question arises: Does the way of thinking about angles have an influence on the way of thinking about sine? Because of this important link between angle measure and the different ways the sine can be defined one can assume that a better understanding of radian measure can help with the understanding of Unit Circle Trigonometry.

## Research design

The goal of this study in progress is to find out more about the network of GV regarding Trigonometry, in particular find answers to the following questions: What GV do students actually have about sine? How are the different GV of sine connected to each other? Are there GV of other mathematical objects that have an influence in the way students think about sine?

This study will be conducted with pre-service mathematics teachers at the beginning of their academic studies that most likely already had a learning cycle in Trigonometry within their school curriculum. The study will be conducted in two phases. The first phase consists of a written test that gives information over the general abilities and GV that students have developed, concerning the area of Trigonometry. In the second phase the students will be interviewed to get deeper qualitative insight in the way students think about sine and angle measure.

The test is composed of twelve questions that are subdivided into four Categories. Three Categories are attributed to different GV namely the Proportion-GV, the Unit-Circle-GV and the Oscillation-GV. The fourth Category contains three open questions. Every Category has therefore three questions on different difficulty-level. With this test-design it is possible to check if certain GV are present in the students mind and moreover on what level they can work with this GV. The open questions can be solved with reference to various GV and are used to check for dominant GV. The test measures the students' abilities to compute and approximate values of sine, their knowledge about degree and radian measure, as well as their ability to solve exercises on triangles, the unit circle and the function graph. Depending on the scores in the test and the reported GV of sine a preferably wide range of different subjects will be chosen to conduct the interviews.

The test includes open questions as well as questions that can only be solved if the students have access to explicit GV of sine. I want to give a small sample of questions that were used in the test. Some of those were taken from the study of Brown (2005) others developed over time in a course of didactics of analysis. One question that seems to be a good indicator for GV that are accessible to the students is: "Estimate the value of  $\sin(80^\circ)$ ". This question can be solved by the students with reference to the unit circle, right-angled triangles or the graphical representation of the sine-function. Another estimation includes radian measure: "The Radian measure of an angle  $\alpha$  is exactly 3. Estimate the value of  $\sin(3)$ . Justify your estimation". In this case not all GV of sine can be used. Moreover, an understanding of the radian measure is needed.

The interviews will be semi-standardized with questions concerning the GV of the students and tasks in which multiple GV of sine need to be activated. In particular, the derivative of the sine-function will be discussed, because it can be approached in various ways. It is possible to justify the connection between the sine function and the cosine function as its derivative with the Proportion-GV, the Unit-Circle-GV and the Oscillation-GV. A very fertile visual Justification is delivered through the Representation of sine in Figure 3. For this argument to be fully understood, students need to be able to switch between the different GV of sine. Moreover they need a good understanding of the derivative as the slope of the tangent and as an instantaneous rate of change.

Figure 3. Visual Justification for the derivative of the sine function

## First results

First of all, the answers of the students show that the concept definition of sine contains various ideas and GV. When asked what sine means to them, answers often include the mention of Wave-functions and the unit circle. Others describe sine as a tool to determine unknown lengths of sides in a right angled triangle, or gave formulas including complex numbers. These responses could be linked to the four GV of sine mentioned above.

Although the students had good explanations for what sine meant to them in general, when they were asked what precisely  $\cos(\pi)$  means to them, most of the answers only included guesses of the values of  $\cos(\pi)$ . These guesses included -1, 0 and 1 but made almost no connection to their GV of sine. A similar result was found when the students were asked to estimate the value of  $\sin(80^\circ)$ . Out of 30 students only five could give a correct answer and only two provided an explanation for their correct estimate. Some guesses for  $\sin(80^\circ)$  included values higher than 1 and even values given in terms of  $\pi$ . It seems that the students had a vague concept of sine and that it was difficult for them to establish a connection between their definition of sine and the calculation of sines for given angles.

Another difficulty arose when the students were asked what the difference between radian and degree is. Some students openly admitted that they had no idea, while others tried to infer meanings from the words. Overall the answers represented the confusion of the students concerning the terminology, although some could convert radian measure into degree measure. Similar results have been found in the study of Fi (2003) and Akkoc (2008). Some students just regarded degree and radian as buttons on a calculator that need to be pressed. Another answer confirms findings of Akkoc that say, that students only consider numbers in radian measure, when there is  $\pi$  involved. A repeating error of students involves the mentioning of  $\pi$  in the output of the sine-function.

Figure 4. an angle of  $53^\circ$

One question in particular provided indications to the statement of Thompson (2018) that for some students the sine function only takes triangles and not angles as an argument. When presented an angle of  $53^\circ$  as shown in Figure 4 with the task to identify  $\cos(\alpha)$  and  $\sin(\alpha)$  graphically, 13 out of 30 students were not able to give a correct answer though some of them used the Proportion-GV in other questions. In some of the answers students replied, that it is not possible to identify the wanted quantities with this figure, because they couldn't find a right-angled triangle. Another common mistake was that students chose to connect the ends of the line segments and ended up with an isosceles triangle instead of a right-angled triangle. Even though the students had

access to the correct GV, they couldn't use it in this context. This shows the need of building up flexible and sustainable GV.

## Discussion

The first collection of data showed that students can operate with various GV on different difficulty levels. It will be interesting to know why some students can operate with a certain GV on a basic difficulty level, but could not advance to a higher difficulty level. The last example seen in Figure 4 shows that some GV are linked to special situations and cannot be used when different mathematical objects are involved. It remains to be seen if these difficulties are just singular observations or if there is a pattern. To confirm that students possess and use the GV on different levels it is necessary to conduct further research and to collect data from more students that are willing to participate in interviews. In this respect it is more likely to reveal the true thinking process of the students in a conversation. A second phase of the investigation, with a revised test and follow up interviews is already planned.

*Keywords: Prospective elementary teachers, geometrical tasks, problem solving.*

This poster focuses on the development of prospective elementary teachers' problem-solving capacity and, particularly, on geometric problem solving. More specifically, we present some preliminary results of a research project that is being developed, in a Portuguese School of Education focusing prospective elementary teachers' preparation in geometry and measure, one of the disciplines of their bachelor's degree.

### Theoretical framework

Recent recommendations for mathematics teaching highlight that effective teaching of mathematics should involve students in "solving and discussing tasks that promote mathematical reasoning and problem solving and that allow multiple entry points and varied solution strategies" (NCTM, 2014, p.10). In the context of the development of "mathematical proficiency" (Kilpatrick, Swafford & Findell, 2001) of students, it is essential that the teacher develops "the ability to see the mathematics possibilities in a task" (idem, p. 370) as well as the capacity to propose tasks that promote reasoning and problem solving. The teacher must also be able to interpret what students do and say, to analyze their reasoning and to answer to the different approaches they use to solve a mathematical problem (Kilpatrick, Swafford & Findell, 2001). However, this is a challenging task, even by experienced teachers since often it is very difficult to interpret some students' solutions, either because they are not expected or because they do not look at them through the students' eyes. In this sense, we believe that to offer prospective teachers the opportunity to produce more than one solution to the same problem, can help them to develop a 'lens' to interpret their future students' problem-solving solutions and to use this understanding to help these students to develop their mathematical proficiency.

## Research question and method

This poster reports part of a research that aims to investigate prospective teachers' capacity to produce and analyse different solutions to solve mathematical problems. This research has an exploratory design framed by a qualitative methodology (Patton, 2012). The participants are 39 prospective elementary teachers organized within two classes, that were inscribed in a Geometry and Measurement course (first semester, second year of the bachelor's degree).

The study had three main phases. At the beginning of the GM course, the prospective teachers were asked to solve a diagnosis test, composed by six problems, using, if possible, more than one strategy to solve each one. To solve the problems, they had to mobilize only geometrical contents of the mathematics curriculum of primary, upper primary and middle school. Throughout the GM course, pre-service teachers were challenged to solve problems that could be solved using different strategies and the teacher, the first author of this poster, promoted and supported collective discussions of these strategies. At the end of semester, the preservice teachers were asked to solve a second test with five problems, and, in some of them, to use more than one strategy.

Data includes pre-service teachers' solutions of the problems, field notes focused on the development of the GM course and transcriptions of excerpts of video recorded collective discussions. In this poster we present only the analysis of the data related to the prospective teachers' solutions of the problems.

## Results

The results revealed that (i) initially prospective teachers expressed many difficulties in solving geometric problems and even more in to use more than one strategy to solve the same problem; (ii) there has been some progress, although incipient, concerning the production, by the future teachers, of more than one strategy to solve the same problem; (iii) the opportunity to solve problems and to analyze different strategies that can be used to solve each problem, helped the participants to improve their mathematical proficiency in the domain of Geometry and Measurement.

*Abstract.* In this contribution, we intend to revisit the interplay between geometrical paradigms GI and GII in the context of the current French curriculum, which gives an important place to modelling activities in mathematics learning. We asked master students to perform a geometric modelling task on the estimation of the area of a field. The resolution of the task requires an articulation between GI and GII by considering measurement and approximation. From this first study, it results that the vast majority of students have developed a geometric work in the GI paradigm by mobilizing a low use of the classical property-based proof discourse. These results question teacher training and, more broadly, the today's mathematics teaching in France.

*Keywords:* Geometrical paradigms, Teachers training, Mathematical Working Spaces, Geometry teaching and learning

## Presentation and motivations of the study

In this contribution, we revisit the issue of teaching geometry in teacher education, which was the subject of several of our presentations at the CERME conferences in the early 2000s. These presentations enabled the development of the theoretical and methodological framework of geometrical paradigms and Geometric Working Spaces, which is used to describe the forms and conditions of geometric work that is performed by students with the help of their teachers.

Kuzniak and Rauscher (2011) provide a classification of the solutions given by pre-service teachers to a geometry task. The main authors' objective was to raise students' awareness of the interaction between geometrical paradigms GI and GII (see next section). However, their study shows that primary school teachers were not very receptive to this interplay because they were confined to the first paradigm GI. Only secondary school teachers, more experienced in mathematics, understood the relevance of this interaction between paradigms. In the study, it was also questioned the difficulties that future primary school teachers had in teaching geometry because of their often deficient or old knowledge in the field. The goal was both to consolidate their knowledge and make them aware of the existence of several geometric paradigms leading to different forms of validation. It seemed interesting to us to review this work in consideration of the evolution of French curriculum, which has undergone notable fluctuations in recent years. The part given to geometry in education decreases significantly throughout the compulsory curriculum and its teaching is now mainly based on calculation and application, most often mechanical, of Pythagoras and Thales theorems, which are increasingly used to practice algebraic computation techniques. At the same time, more emphasis is put on modelling activities. In addition, from an institutional point of view, primary school teachers are now trained at university and must obtain a specific master's degree in education whereas previously they followed a two-year non-degree vocational training course after passing a competitive examination.

More specifically, this research has two types of objectives that concern students who want to obtain a master's degree in primary education:

- identify the geometric work actually produced by these teacher students in order to understand it and eventually be able to influence it.
- make these students aware of the measurement and area issues in relation with the geometric paradigms GI and GII with the possible interplay between these two paradigms.

In this new study, which extends our recent studies on the teaching of geometry (Kuzniak and Nechache, 2015), teacher students had to perform a geometric modelling task on the estimation of the area of a field. This research is part of a larger project that aims to investigate mathematical work in various institutional contexts. The analysis of students' geometric work is supported on the previously used research framework which, and this is also one of the motivations of this new study, had largely evolved towards what is now referred to as the theory of Mathematical Working Spaces (MWS).

## **Theoretical and methodological elements**

As this research is based on the theoretical framework of Mathematical Working Spaces articulated with the notion of geometrical paradigms, we will briefly outline the main elements of this theory by referring the reader who wishes to know more about it to the literature on the subject, especially that of previous CERMEs.

### **Geometrical paradigms**

According to Houdement and Kuzniak, (2006), in the context of teaching, it is possible to identify three geometrical paradigms named respectively GI, GII and GIII. By taking up the presentation made by Kuzniak (2018) we can introduce them in this way:

“The paradigm called Geometry I is concerned by the world of practice with technology. In this geometry, valid assertions are generated using arguments based upon perception, experiment, and deduction. There is high resemblance between model and reality and any argument is allowed to justify an assertion and to convince the audience. Indeed, mechanical and experimental proofs are acceptable in Geometry I.” (Kuzniak 2018, p. 10)

“The paradigm called Geometry II, whose archetype is classic Euclidean geometry, is built on a model that approaches reality without being fused with it. Once the axioms are set up, proofs have to be developed within the system of axioms to be valid. The system of axioms may be left incomplete as the axiomatic process is dynamic and has modelling at its core.” (Ibidem, p. 10)

Both geometries, I and II, have close links to the real world, albeit in varying ways. In particular, they differ with regard to the type of validation, the nature of figure (unique and specific in Geometry I, general and definition-based in Geometry II) and by their work guidelines. To these two Geometries, it is necessary to add Geometry III, which is usually not present in compulsory schooling, but which is the implicit reference of mathematics teachers who are trained in advanced mathematics. In Geometry III, the system of axioms itself is disconnected from reality, but central. The system is complete and unconcerned with any possible applications to the real world. (Ibidem, p. 11)

The identification of geometrical paradigms contributes to the understanding of the epistemological nature of the work actually produced in a school institution. The study of the circulation of

geometric work within the Mathematical Working Space will provide a more fine-grained characterization of this work.

### Mathematical Working Spaces

The theory of Mathematical Working Spaces (Kuzniak, Tanguay and Elia, 2016; Kuzniak and Nechache, 2015), known as MWS, aims to analyse the mathematical work produced by students or teachers in a specific educational institution. Mathematical Working Spaces are designed and thought out in such a way that their users can carry out their work under conditions that promote the emergence of a coherent and complete work. In this theory, mathematical work is structured through the interactions of epistemological and cognitive planes:

- the epistemological plane, composed of three poles: representamen, artifact, theoretical reference frame. It is used to structure the mathematical content of tasks.
- the cognitive level, composed of three cognitive processes: visualization, construction and proving. It reflects user's cognitive activity during task resolution.

The move from one plane to another is ensured by a set of geneses linked to the poles: a semiotic genesis based on the registers of semiotic representation that gives the tangible objects of the MWS their status of operative mathematical objects; an instrumental genesis, which has for function to make the artifacts operative in the constructive process; a discursive genesis of proof, which allows to give meaning to the properties to be implemented in the mathematical reasoning.

These three geneses facilitate the circulation between the two planes by stimulating an articulation between the respective components of the two planes. This set of relationships can be visualized by means of a diagram in the form of a triangular-based prism.

The analysis of geometric work can therefore be done through one of the three dimensions associated with each of the geneses (semiotic, instrumental and discursive), or through the articulation of two of them: semiotic and instrumental ([Sem-Ins]), semiotic and discursive ([Sem-Dis]), or discursive and instrumental ([Dis-Ins]). These different articulations thus define three vertical planes (Figure 1).

Figure 1. The three vertical planes of the MWS (Kuzniak & Nechache 2014)

The use of these different vertical planes helps to specify the circulation of geometric work in the MWS and the manner in which geometric work is carried out.

## The task “Le terrain d’Alphonse”

### Experimentation

To carry out the research, the task "Le terrain d'Alphonse" was assigned to two groups of undergraduate and master's students (45 students), who intend to teach in elementary school. The implementation of this task was performed in three phases. In the first phase, the task statement is given to the students in the form of a text to be read.

Alphonse has just returned from a trip in Périgord where he saw a field in the shape of a quadrilateral that had interested his family. He would like to estimate its area. To do this, during his trip, he successively measured the four sides of the field and found, approximately, 300 m, 900 m, 610 m, 440 m. He's had a lot of trouble in finding the area. Can you help him by indicating how to do it?

The purpose of the first phase is to specify that there is a lack of data to establish the exact shape of the quadrilateral that Alphonse wants to know the area. In the second phase, the length of a diagonal (630 m), without specifying which one, is given to the students to discuss the shape of the quadrilateral: convex or non-convex, crossed or not. Finally, once the shape of the quadrilateral has been decided, the third phase is devoted to concluding the resolution of the task. In each of the three phases, after collecting the students' written productions, we proceeded to a pooling. These exchanges allow us to list all the methods used by the students on the blackboard in order to discuss them. In particular, the results obtained are compared in relation to the selected shape of the terrain and the methods used to calculate the area.

Several methods can be used to achieve this task and they involve different geometric paradigms depending on both curriculum expectations and the students' personal work. The resolution of this task requires a modelling approach and involves work on approximation issues related to measurement.

### Collection and analysis of data

To conduct our research we collected the students' written productions (45 productions for each phase, for a total of 135 productions). We also recorded and transcribed the exchanges that occurred during the pooling.

The students' written productions were studied by using a grid specifying the type of work done on the figure(s) and the types of discourses related to the area and its measurement. The analysis of the recordings of the pooling complements the analysis of productions and helps to refine student profiles. With the help of a statistical analysis software, we were able to identify five groups of students providing different forms of geometric work. Given the size of the present paper, we have limited ourselves to presenting briefly only four of these forms of work.

### The expected geometrical work in master

A teacher trainer was solicited to implement the task in her group. She solved the problem informally before giving it to her students and her reasoning is in line with the work expected from the students who want to pass the competitive examination which presupposes knowledge of the geometry taught at the College (Grade 6 -9). She immediately detects that a data is missing and asks

for a diagonal. Using the value of a diagonal (630 m), she starts by constructing the quadrilateral with ruler and compass (instrumental dimension) to get an idea of its shape (semiotic dimension). She draws the figure using a scale that matches 1 cm on the figure to 1 m on the field. Thus, her work begins in the [Sem-Ins] plane with the intention of using a configuration as a support for the reasoning. She then deducts two possible forms of the quadrilateral, one convex and the other not convex<sup>1</sup>. Then, she suggests to start by determining the area of the terrain with a convex shape. Her choice is motivated by the fact that, in this case, the task is easier for the students. To achieve the task, she makes a freehand drawing and decomposes the quadrilateral into two triangles. On the drawing, she specifies known and unknown values used to calculate the height of each triangle thanks to Pythagoras's theorem (discursive dimension). The work of proof is then based on algebraic computation with a strong numerical component. The freehand drawing becomes a support for algebraic calculation (semiotic dimension) by avoiding any direct measurement.

The mathematical work expected from preservice school students at the master's level can be summarized as follows:

1. The work is initiated in the [Sem-Ins] plane in order to distinguish the different cases that may exist. Work is guided by elements of the theoretical referent relating to the quadrilateral: various forms of the quadrilateral and importance of the diagonal to determine the nature of the quadrilateral.
2. The technique of triangulation is completely integrated in work (still in the [Sem-Ins] plane) but it is not explicitly mentioned. Perhaps this is due to the fact that the diagonal line shows the triangles directly and to the non-formal nature of the proof given by the teacher's trainer.
3. Work then moves to the [Sem-Dis] plane associated with algebraic work supported on the freehand figure and on Pythagoras's theorem used as a theoretical tool that switches work to algebraic work without any measurement on the drawing. The whole challenge of proof by calculation that is then made is to avoid any appeal to measurement.

This work is in accordance with the paradigm expected at this school level, which is a paradigm articulating GI and GII insofar as the reasoning is based on a particular figure without any generalization and on approximate values by prohibiting any effective measurement on the drawing.

### **Different forms of geometric work identified**

In the following, we only present the results of the first phase which, contrary to our initial expectations, followed an unexpected and longer course. Indeed, almost all the students did not identify the need for asking additional indications and they engaged in the search for the area by adding certain conditions such "The quadrilateral had to be particular" or "All the quadrilaterals with the same perimeter have the same area". These assumptions allow them, therefore, to reason on a particular figure. We present below four of the different forms of geometric work that we have identified at the end of this phase.

---

<sup>1</sup> We leave aside the case of a diagonal outside the quadrilateral or the crossed quadrilaterals that appear, in this modelling exercise, as two triangular fields and not as a quadrilateral.

### Form 1. An asserted work of measurement: Francis' work

Francis begins his work with a scale construction with ruler and compass where he gets a trapezoid based on visual adjustment, guided by the idea that the figure should be particular (Sem-Ins).

Francis: I took the large 900 m base then from both ends with the compass, I made 410 on one side and 610 on each side and then with the ruler I tried to find the 300 with the two arcs of circle.

He then justifies why, it is indeed a trapezoid by relying on a geometric property of the theoretical reference frame, discursive dimension, (Sem-Dis).

Francis: I have drawn a perpendicular to the large base and this line was also perpendicular to the small one and since the two lines are perpendicular to the same line, they are parallel to each other so it makes a trapeze.

Finally, he completes his work in the [Ins-Dis] plane with calculations using formulas and by measuring the missing data on the drawing. He explains that he can do this because he has done his figure using a scale. His mathematical work is valid in the GI paradigm and moreover, as we will see again later on, this work is assumed by the student.

### Form 2. A geometric work structured around the instrumental dimension: Ivana's work

This work is representative of the work done by students who have used geometric drawing tools by attempting not to use measurement too explicitly. The mathematical work produced by Ivana was initiated in the [Sem-Ins] plane to construct a quadrilateral (ABCD) by means of geometric drawing tools and with the assumption that one of the angles of the quadrilateral was a right angle. This inclusion of an additional property is common among students who have chosen to use drawing tools.

Ivana : In fact I constructed the figure to have a right angle, and so I calculated the area of the first triangle by doing (...).

Then, she decomposes the resulting quadrilateral into two triangles (Sem), one of them ABC is general and the second ADC is right-angled in D so that she can apply the triangulation method (Dis) to determine the area of the quadrilateral as the sum of the areas of these two triangles. Thus, mathematical work is located in the [Sem-Dis] plane. The, she calculates the area of the rectangular triangle ADC in D, then she applies the Pythagoras theorem (Dis) in the same triangle to deduce the length of its hypotenuse [AC]. Finally, Ivana uses the graduated ruler to measure a length (the height of the triangle ABC from B) and she applies the formula of the area of a triangle to determine the area of the triangle ABC. The mathematical work thus ends in the [Ins-Dis] plane with an unspecified use of measurement. Therefore, we can say that the mathematical work is complete and that it is guided by the GI paradigm.

However, this work does not conform to "mathematical rules" since the student has no control over the results obtained. When the professor asked her about the validity of her work, she answered that "all the quadrilaterals have the same surface because they have the same perimeter" and that is why it is possible to reason on a particular figure. This "theorem in action" leads to the fact that her mathematical work is not valid or conform. With this work, we are faced with a fairly common

problem of interpretation about the identification of the exact paradigm in which the student works. Students, because of the very strong didactical contract at this level, generally avoid measurement and thus think they work in the GII paradigm. But, in fact and in part to avoid obstacles linked to the difficulty of giving a proof based solely on properties of the frame of reference, they surreptitiously move into the GI paradigm either, as Ivana, by using measurements not assumed or as we will see below by using data based on perception only.

### Form 3. A work without measurement and without theoretical control: Katia's work

The following geometric work is one of the most frequent among students who did not want to use construction instruments. They forbid themselves measurements on the drawing and wish to work in GII but nevertheless they allow themselves a great semiotic freedom to obtain formulas or apply known area calculation formulas.

Let's illustrate this approach with Katia's production. She begins by drawing two freehand figures (Sem), suggesting a transformation from the first to the second that leaves the area of the figure, more or less, invariant.

Figure 2: Katia's work

Katia then explained that one has to take the initial lengths and imagine that the terrain is a rectangle. To determine this area, she applies the technique giving this value by multiplying the lengths of the two sides (Ins). The lengths of each new sides are obtained as an arithmetic average of the opposite sides. Thus, the work is located in the plane [Sem-Ins] because it is oriented towards the use of a well-known area calculation formula by transforming the initial geometric figure. This work is produced without any control by means of material tools (geometric instruments) and theoretical tools (properties). Therefore, if this geometric work may be considered as partially valuable in GI it is not valid in any of the paradigms.

### Form 4. A geometric work initiated in GII but unfinished: Severine's work

This form of work was rare in both groups and initiated by students with a good level in mathematics. In her work, Severine starts by producing a free-hand dissection of the quadrilateral into a trapezoid and two rectangle triangles (Sem). She explains her procedure in this way:

Séverine: I started from a general quadrilateral and then I drew two right-angled triangles (inside) in order to complete the quadrilateral.

Then, she explained that it would be necessary to find the heights of the triangles and also to use Pythagoras theorem to do the calculations (Dis). She intended to do this work but she did not perform it. However, at this stage, this can be considered normal because a data is missing, but she did not asked for it. She was thus blocked in the plane [Sem-Dis] and the teacher intervened by trying to motivate the claim of a diagonal.

Teacher: Can you comment on what Séverine suggests, do you have the necessary information to do the calculation

Students then request additional data on measurements but do not ask for the length of the diagonal. Francis intervened once again by indicating that it is possible to measure on the drawing because it was made with a scale. Séverine does not agree with him and she refuses to measure on the figure (GI paradigm) preferring to remain blocked and not complete the task.

## Conclusion

In this preliminary study, which is part of a more global research project on teacher training in geometry, we were able to identify some different students' forms of geometrical work when they have to achieve a geometrical task which relates to the estimation of the area of a field. The results we have obtained show blockages and rebounds among students who are trying to meet institutional expectations (a geometric work in GII). The work they produce is profoundly incomplete because it is often confined to a single plane or dimension of the MWS. Moreover, and for us, it is the most worrying from the teacher education viewpoint, these teachers students do not seem to have control tools on their productions other than perceptual and instrumental. When they have tried to use theoretical controls, there were generally based on false "theorems in action" that do not ensure the validity of mathematical work from an epistemological perspective. It should be pointed out, however, that the situation is destabilizing for the students because it does not follow the usual didactic contract, which implies that all the data needed to solve the problem have to be included in the task statement. Moreover, almost all the teacher students think that all the geometric shapes they are asked to study must have some particular shapes and properties. And, on their own initiative, they suppose that the quadrilateral has a specific property (right angle, parallel sides...) which allows them not to be blocked in a dimension or plane of the MWS but it results that their work cannot be considered to be valid. From this observation, we intend to develop didactical situations that ensures a first exploration work on drawing in order to question the construction and validation methods within a geometry I that promotes both modelling and controlled approximation work.

*We study proving situations in geometry where students introduce auxiliary lines. We examine students' reasons for introducing auxiliary lines. The overarching theme of the tasks proposed to the students is the comparison of areas of triangles and/or parallelograms. The students gave a wide spectrum of reasons when introducing auxiliary lines. Two main groups of reasons have been discerned for modifying a given situation by introducing auxiliary lines: recalling a learned procedure using some known results or definitions, and anticipating more information from the modified situation. We present a case study of a pair of students who combine reasons of recalling and anticipating nature when introducing auxiliary lines.*

**Keywords:** High school geometry, proof, auxiliary lines, reasoning, task-based interviews.

## Introduction

The objective of this study is to contribute to research on proving in geometry. Specifically, we investigate the introduction of auxiliary elements by students while proving and characterize reasons students give for their actions. Our interest in this process stems from the following facts: First, proving in geometry is difficult for students in general. Second, the introduction of auxiliary lines contributes substantially to students' difficulty with proofs in geometry (e.g. Hsu, & Silver, 2014; Senk, 1985). Our focus on students' reasons for introducing auxiliary elements led us to build on the seminal work of Pólya (1957), who highlighted the role of auxiliary lines in problem solving.

## Theoretical background

It is widely recognized that in secondary school, proof and proving are still mostly taught in the area of geometry (Herbst, 2004; Fujita & Jones, 2014). According to Battista (2007) school geometry presents students with a complex network of concepts, representations and ways of reasoning "...that is used to conceptualize and analyze physical and imagined spatial environments" (p. 843). Combining deductive and spatial reasoning is pertinent to proving activities in geometry. Indeed, in his study of American geometry classes, Herbst (2004) demonstrated, among others, a *generative* type of students' interaction with diagrams in proving activities. Such interactions are characterized by deductive reasoning interrelated with modification of a given diagram. Such interactions are virtually absent from geometry classes, as studies of Japanese secondary schools confirm (Miyazaki, Fujita, & Jones, 2015) but are central for proofs that require the introduction of an auxiliary element.

According to Pólya (1957), "an element that we introduce in the hope that it will further the solution is called an auxiliary element" (p. 46). In our study, a slightly expanded version of this definition is used. Namely, we consider also the modification of an already existing element as an auxiliary element (see Task 1 in the Methodology section). Moreover, an auxiliary element may be only imagined rather than physically drawn.

According to Senk (1985) the introduction of auxiliary lines is a critical part in the solution of geometric proof problems. She concluded that the difficulty with auxiliary lines “exemplifies the need to teach students how, why, and when they can transform a diagram in a proof” (p. 455). Ding and Jones (2006) also identified the introduction of an auxiliary line as a source of great difficulty. Hsu (2007) claims that this difficulty is caused by students’ need to perceive the diagrams dynamically and apply transformational observation to visualize a solution achievable with auxiliary lines.

Students’ difficulty with introducing auxiliary lines when proving can be partially explained by a form of instruction, which does not encourage students to add new lines to the given diagram. For instance, students in the study of Herbst and Brach (2006) self-reported that they expect to play a passive role in interaction with diagrams when proving: They believe that they are usually not expected to introduce auxiliary lines, and if so, they expect to receive a hint to do so from the teacher. This difficulty may be overcome by the incorporation of various types of exploration in proving which makes the introduction of auxiliary lines more transparent (e.g. Fan, Qi, Liu, Wang and Lin, 2017).

Considering these studies and Pólya’s fundamental work, it makes sense to consider the introduction of auxiliary lines through the prism of reasons that led to their introduction. Pólya (1957) lists three main reasons for introducing auxiliary lines (p. 46):

- 1) Trying to use known results;
- 2) Going back to definitions;
- 3) Expecting to make the original problem “fuller, more suggestive, more familiar”.

Pólya makes a distinction between the first two reasons and the third one. He states that in the third case “we scarcely know yet explicitly how we shall be able to use the elements added. We may just feel that it is a ‘bright idea’ to conceive the problem that way with such and such elements added” (ibid.). In our study we sought both, to obtain descriptive reports about students introducing auxiliary elements in proving situations, and to identify the types of reasons they provide for introducing them. We adapt Pólya’s classification to our aims by introducing the terms *recalling* (Pólya 1, 2) and *anticipating* (Pólya 3) reasons.

Given this background, our research aims to answer the following questions:

- A. What reasons do the students give when introducing an auxiliary line in a proving situation?
- B. To which type do these reasons belong, recalling or anticipating?

## Methodology

### Students and Tasks

The participants in our study were high school students studying geometry in Grade 10—the first grade of Israeli high school. Eighteen students were nominated by their mathematics teachers; ten of them volunteered for the study. The students were grouped into five pairs, following Schoenfeld’s (2000) suggestion that students working in pairs will show reliable and natural behavior.

We sought to create tasks where students would be inclined to draw auxiliary lines in order to make progress. We anticipated that tasks with multiple solutions, each based on different auxiliary lines, will elicit a variety of reasons for introducing auxiliary lines. The topic of areas was suitable as it was

already known to the students, but proofs on areas had not been taught in class at the time of the intervention. We used two tasks with different levels of complexity.

Task 1: Quadrilateral ABCD is a parallelogram. Where on side AB do you have to place point E, so that the area of triangle DEC is a half of the area of the given parallelogram ABCD? Explain your reasoning.

There are multiple ways to show that E can be anywhere on side AB. Figure 1 hints at some of them, highlighting the role of appropriate auxiliary lines in the proofs.

**Figure 1. (a-c) Task 1 with auxiliary lines, (d) students' sketch**

Task 2: Prove that the quadrilateral formed by the midpoints of the sides of a given quadrilateral is a parallelogram, and that its area is half of the area of the given quadrilateral (Varignon's theorem, Theorem 3.11 in Coxeter & Greitzer, 1967). Task 2 contains two parts, the second of which relates to area. This two-part structure and the large variety of possible auxiliary lines allowing to make use of properties of a triangle's midsegment and of a parallelogram to prove the claim make it especially suitable for our study (see students' sketches in Figure 2 in the Findings section).

## Procedure

We used two interview techniques to obtain information on the introduction of auxiliary lines: *stimulated recall* (SR) and *partial revealing* (PR). SR is a reflective method used in qualitative research (e.g., Bikner-Ahsbabs, 2004) in which students carry out a task undisturbed and are later prompted by the use of some visual or auditory stimulus to recall their thoughts while carrying out the task. A crucial advantage of SR is that it does not interfere with carrying out the task. Thus, we decided to use SR in the relatively simple first task. Also, the SR sessions which followed the first task familiarized students with the researchers' request to reflect upon their actions.

In the more complex Task 2, we wanted to make sure that students do not get stuck. For this purpose, we developed and used the idea of partial revealing (PR), a variation on task-based interviews (Goldin, 2000): We prepared a progressively more revealing sequence of 12 visual or verbal hints. The hints were descriptions/ sketches of an auxiliary line or some key idea/ definition, supporting different ways to prove Task 2 (cf. hints to the same problem in de Villiers, 2014). The hints helped students recalling relevant knowledge or focusing on specific information given in the problem. After obtaining a hint, the students were encouraged to reflect upon the new situation created by the hint. This approach helps the students (and the researcher) to understand and describe the possible reasons for introducing an auxiliary line, whether they tried to use a definition, a previously solved problem or just feel that the hint will advance the proof.

In a first meeting (about 20 minutes), each pair of students worked on Task 1 (Figure 1) without researcher intervention. The solution, explanation, or proof, agreed upon by the two students was collected by the researcher without comment. In the second meeting (about 45 min), two days after the first one, the student pairs returned to Task 1, using SR. In the third meeting (about 45 min), the students worked together on Task 2. The PR method was applied.

The qualitative analysis of the data was based on the methodology used by Jones (1998) for the exploration of students' solutions of geometric construction problems on the subject of interplay between students' intuitive and deductive reasoning. First, the video-recordings of all interviews and the students' written productions were searched for auxiliary lines drawn by the students. Then, the videos were transcribed; we read the transcripts of all the meetings line by line, and marked phrases that seemed to relate to reasons for adding auxiliary elements. Next, students' actions and utterances while introducing the auxiliary lines were coded according to our adaptation of Pólya's (1957) list of reasons for introducing of auxiliary lines. For instance, the utterance "The subject of the problem is an area, we need to draw the height" which accompanied introduction of the line segment EF (Figure 1c) was coded as "recalling" (going back to definition/ concretizing a formula). The utterance "It just seems right to draw this line" about the same auxiliary line was coded as "anticipating" (expecting to make the original problem more suggestive). These broad categories of reasons were further divided according to the type of auxiliary line and the type of reason.

When analyzing Task 1, we juxtaposed students' explanations during the SR sessions with their explanations to their partners during the problem-solving meetings and with written productions and sketches. We paid special attention to the general context of the proof and in particular to the change in students' actions and utterances after introducing the auxiliary line; in this, we followed Goldin's (2000) way of analyzing interactions between the subjects and mathematical structures of the tasks. This procedure helped us to confirm and elaborate our initial coding.

When analyzing Task 2 we paid special attention to the moments where specific PR hints (definitions, formulas or visual images) led to the introduction of an auxiliary line; again we followed Goldin (2000), this time with respect to the role of hints in the analysis of students' problem-solving behavior.

## Findings

We analyzed five pairs of students. Here<sup>1</sup>, we present the case of Bob and Boris whose reasons were of both types: "recalling" and "anticipating".

### Task 1

Boris soon drew the auxiliary line GF (Figure 1d) stating: "I want to calculate the area of CED and then the area of the two smaller triangles, to compare." In the SR session, he described GF as a height through the midpoint of AB, and gave the following reasons for the introducing GF: "Because they ask for area, and the height is a part of the area formula" (Bob&Boris SR10). When asked about the reason for drawing the height exactly at the midpoint of AB, Boris can't give a specific reason: "It was the first point to draw the height"; "it was an initial thought" (Bob&Boris SR 28, 36). In the SR

---

<sup>1</sup> Analyses of two more cases are presented elsewhere (Palatnik & Dreyfus, 2018)

session Bob recalled that immediately after Boris drew the auxiliary line, he thought that there are probably more places where the area is the same.

The students' solution of Task 1 culminated in the following exchange:

- Boris: The height will always be the same!
- Bob: Let's assume that I place it, point E, together with point A [Points at the sketch, draws imaginary AC].
- Boris: [loud] Look, it is at every point!
- Bob: [continues with confidence] So, it happens at every point.
- Boris: The base is the same base, and the height is the same height, so at every point it will be equal.
- Bob: U-hu, if I place it there, at point A (draws imaginary line AC=EC), it is diagonal, it halves the parallelogram. If I place it at the point B, diagonal BD also halves the parallelogram.
- Bob: So, it looks to me, that at every point. (Bob&Boris M1 35-41)

*Analysis of Task 1.* The auxiliary elements introduced by the students in the course of solving the task were: (1) GF—the height through the midpoint of AB; (2) and (3) diagonals AC and BD (imagined). As follows from the students' explanation given above, the reason to use height was that it forms part of the formula for the area and thus of *recalling* nature. A possible explanation for the choosing the height through the midpoint of the side is the intuitive rule same A- same B (Stavy, & Tirosh, 2000), namely, half of the area (A) - half way on the side (B). As for the diagonals AC and BD, Bob imagined them and gestured them in the air. In the SR session, he explained that if E is placed at the vertices A and B it's easy to see that the diagonals AC and BD halve the parallelogram (anticipating).

## Task 2

The students started by drawing their own sketch (Figure 2a). Boris soon focused on the second part of the task: the area of the parallelogram is half that of the quadrilateral. Bob drew EG, a height in ABCD, as first auxiliary line, but the students realized that they do not know a formula for the area of a general quadrilateral. They received as hints (a) an accurate sketch of the task; (b) a drawing of a triangle with a midsegment. The midsegment immediately triggered progress. Boris drew the diagonals AC and BD, and Bob formulated a full formal proof to the first part of the task, using the property that a midsegment of a triangle is parallel to the third side of the triangle.

To prove the second part of the task, the students wanted to calculate areas and looked for a place to construct a height. A switch from calculating to comparing areas was initiated when they attended to pairs of congruent triangles and in particular to the triangles AHN and HDI (Figure 2b, 2c). Bob suggested comparing their areas to that of quadrilateral HIMN, and Boris introduced the crucial auxiliary line NI (Figure 2c).

- Boris: I have constructed a diagonal [of HIMN]. And [points to the sketch] this angle equals this, 'cause it is parallel.
- Bob: No, you still have to prove this.

Boris: Wait a minute [rotates the sheet with the sketch]. We have to prove that these areas are equal [points to the triangles AHN, HDI, NMI and IHN]. It will make it a midsegment (of triangle AMD) (Bob&Boris M3 134-140).

Later the students developed this idea into a proof (Figure 2d).

*Analysis of Task 2.* The main auxiliary elements introduced by the students in the course of task solving were: (1) EG—the segment connecting the midpoints of AB and CD; (2) diagonals AC and BD and (3) NI- the midsegment of the triangle AMD (and the three analogous midsegments in the other parts of the quadrilateral).

2a

2b

2c

2d

**Figure 2. The students' sketches for Task 2 (2c is our copy of a relevant part of students' sketch 2b)**

We may assume that the auxiliary line EG, perceived by the students as a height, was introduced as a part of a recalled procedure which connects between height as an auxiliary line and height as a part of the area formula as previously mentioned by Boris.

The diagonals AC and BD were introduced immediately after the visual hint (a drawing of a triangle with a midsegment). We assume that the hint led the students to *recall* the definition and properties of a midsegment, which became a reason for introducing AC and BD which in turn helped them elaborate the sketch into a formal proof.

We interpret that the reason for introducing the crucial auxiliary line NI was an *anticipating* one. Despite the fact that Boris was not sure how this auxiliary line will advance his proof, he introduced it wishing to show that the areas of quadrilateral HIMN and the combined areas of HDI and AHN are equal. It is remarkable that in the collaborative problem-solving efforts of Bob and Boris in Tasks 1 and 2 the reasons to introduce auxiliary lines were both of *recalling* and *anticipating* nature.

## Discussion

Our aim was to reveal and characterize students' reasons for introducing auxiliary lines in geometric proof situations. The five pairs of students who participated in the study introduced a total of 26 auxiliary elements of various nature: heights of triangles and parallelograms, diagonals of parallelograms, triangle midsegments, and medians. Some of these elements were actually drawn, others imagined. As we expected, Task 2 was not easy for students to prove (cf. Ding and Jones, 2006; Hsu and Silver, 2014 about the complexity of tasks with auxiliary lines).

The reasons students gave when introducing auxiliary elements are of two types (1) recalling some known formulas, definitions and procedures, and (2) anticipating to receive more information from a modified situation. There were 14 auxiliary elements of the first type and 12 of the second.

In the tasks we used, most of the reasons of a recalling nature were related to the introduction of heights. The students drew heights as part of a learned algorithm for finding areas: height is explicitly present in the area formula; hence students recalled the formula, and almost immediately drew heights as auxiliary lines; this seems to be a pertinent feature of students' proving process in the context of areas. It was very salient in the interview with Bob and Boris.

Our data allow us to elaborate on characteristics of Pólya's third type of reason for introducing auxiliary lines: anticipating to make problem fuller, more suggestive, without knowing exactly how the auxiliary line will be used. Most of the examples of such reasons we found can be organized into two groups. In the first group (4 occurrences), we put reasons related to intuitive rules (Stavy, & Tirosh, 2000). Evidence for this is provided by the intuitive "half side-half area" reasoning when introducing the auxiliary lines through the midpoint of the side (e.g., Bob and Boris, Task 1, line GF). In the second group of *anticipating* reasons for introducing auxiliary lines (6 occurrences), we put reasons related to the students' feeling that they exhausted the available resources and they needed to produce some new source of information (e.g., Bob and Boris, Task 2, NI).

All students used area formulas when proving Task 1; a majority also introduced heights in Task 2, and when this failed, they introduced other auxiliary lines. One possible explanation for this is, that when the students felt that they had exhausted the resources suggested by recall, they tried auxiliary lines based on some anticipation, while keeping in mind that they have to substantiate it (as happened to Bob and Boris when introducing NI in the second part of Task 2).

Based on these findings, we suggest that the introduction of auxiliary lines in proving situations can be expected to provide a rich context for the development of geometrical thinking. Teachers should encourage proactive and reflective approaches to the introduction of auxiliary elements. It is impossible to develop mastery related to the introduction of auxiliary lines without creating experiences of drawing, imagining and dynamically modifying auxiliary lines. This study of students introducing auxiliary elements when proving included only a small number of participants, and only two tasks from a single geometry topic, and it was conducted with paper and pencil only. Further research is required to better understand the complex dynamics of introducing auxiliary lines.

# Construction of triangles: some misconceptions and difficulties

Paula Vieira da Silva<sup>1</sup> and Leonor Santos<sup>2</sup>

<sup>1</sup>UNIDEF, Instituto de Educação, Universidade de Lisboa, Portugal; paulasilva@campus.ul.pt

Instituto de Educação, Universidade de Lisboa, Portugal; mlsantos@ie.ul.pt

*This study aims to analyze tasks that involve the construction of triangles and which are included in 6<sup>th</sup> grade national assessment tests in Portugal. More specifically, we analyze the mental processes used by the students, the difficulties experienced and the mistakes made in solving these tasks. The study follows a methodology of an interpretative nature, with data collection from the students' tests, the productions of the students and of interviews recorded in audio. In summary, the results show that, in linear measurement, many students demonstrated a quite acceptable level of sophistication. However, in the construction of angle the causes of their difficulties seem to be the absence of adequate structural components.*

*Keywords: Geometric thinking, construction of triangles, didactic material.*

## Introduction

In constructing a school curriculum it is necessary to make choices, and this need to choose is precisely what makes it so difficult to decide on a coherent and balanced curriculum throughout the period of learning in the school (Mammana & Villani, 1998). In Portugal, these choices are also visible in the emphasis given to certain contents in the 6th grade National Assessment Tests (NAT). In these tests, from 2010 to 2015, a task that involves the construction of triangles was always presented. In the Basic Education Mathematics Program (PMEB) of 2007, in the Program and Curricular Goals of Basic Mathematics Education of 2013 - PMCMEB, and in NAT, the construction of triangles has an obvious centrality. The characteristics of the tasks proposed in the NAT, overestimating certain curricular contents and certain mental processes, can induce the teaching methodologies used by the teachers and, consequently, influence the students' learning, and therefore, their analysis is of great importance. So, the main objective of this study is to analyze the 6<sup>th</sup> grade NAT tasks that involve the construction of triangles. In particular, we consider the following research questions: What mental processes were used by students? What difficulties have been experienced and what mistakes have been made in solving these tasks?

## Theoretical framework

A very particular aspect of the study of geometry is the construction of triangles. The triangle is the simplest flat figure. It comprises, with only three sides, three angles and three vertices, a defined part of the plane. Its simplicity makes it a basic tool for decomposing more complex figures and making measurements, and is therefore considered the basic mosaic of geometry (León & Timón, 2017).

In the process of constructing triangles, the abstraction of the concept of angle and of measurement are essential, since some of the errors produced by the students in the resolution of tasks that involve the construction of triangles are related to the construction of angles given a certain amplitude and with the measurement of line segments.

When constructing triangles with ruler, compass and protractor, various concepts and properties should be used. The previously studied concepts and properties must be related and applied at the time of construction. In the various stages involved in the construction of the triangle,

different difficulties can arise if the properties of the triangles are not taken into account in their construction (Zamagni & Crespo, 2016). The students' difficulties in solving tasks involving the construction of two-dimensional representations of triangles are sometimes also due to the lack of experience and skills in the use of the didactic materials needed for this construction (Van de Walle, 2009). These difficulties are also due to the appeal to their properties and the fact that visualization plays an important role in the decoding and transformation of mathematical information.

### **Understand the concept of measurement**

The concept of measurement is built along the construction of the geometric conceptualization, reasoning and application (Battista, 2007). Based on other authors, Battista (2007) considers that despite the importance of geometric measurement, the performance of some students in measurement tasks is low. That is, they do not adequately establish the connection between numerical measurements and the iteration process of unitary measures. For example, students who incorrectly measure an object's length when one of its edges is not zero-aligned in a ruler do not conceptualize clearly how the numerical ruler marks indicate the iteration of the lengths of the unit. According to this same author, many traditional curricula prematurely teach numerical procedures for geometric measurement, students have little opportunity to think about the adequacy of the numerical procedures they apply and do not have sufficient opportunities to develop skills with spatially structuring units of measurement.

Joram, Subrahmanyam, and Gelman (1998) argue that although younger students can learn some simple measurement skills, real physical measurement, such as determining lengths, for example with physical objects serving as a unit of measure, is a challenge for many, which may mean that students' knowledge of linear measures may be more superficial than it seems.

Battista (2007) integrating investigations that describe levels of sophistication in the development of concepts of measurement of length, developed a characterization of the construction of meaning of the students. In this characterization, there are two fundamentally different types of reasoning about length, *reasoning without measurement* that does not use numbers (involves visual-spatial inferences based on direct or indirect comparisons, imagined transformations of geometric properties) and *measurement reasoning* (involves iteration of units of length, that is, the determination of the number of units of fixed length that fit end to end along the object, without gaps or overlaps). Measurement reasoning includes not only the measurement process, but the reasoning about numerical measures (e.g., adding lengths to find the perimeter of a polygon, making inferences about length measurements based on the properties of the figures). Although students usually develop strategies without measurement before measurement strategies, reasoning without measurement continues to develop in sophistication even after the reasoning of the measurement appears. In addition, a more sophisticated reasoning about length involves the integration of reasoning without measurement and measurement.

The research of several authors suggests that students construct a meaningful understanding of the measure of length as they abstract and reflect on the process of iteration of units of length (Battista, 2007).

## Understanding the concept of angle

Students have great difficulty in learning the concept of angle (Clements & Battista, 1992). Angle is considered to be a multifaceted concept (Douek, 1998), since there is a great variety of definitions presented in school textbooks and textbooks for teacher training (Mitchelmore & White, 2000). Some authors consider that the angle can be defined based on three different aspects: as a quantity of rotation between two lines meet at a point (turn), as a union of two rays with a common extreme point (ray) and as the intersection of two half-planes (region) (Mitchelmore & White, 2000; Devichi & Munier, 2013). This concept is constructed slowly and progressively (Lehrer, Jenkins, & Osana, 1998; Mitchelmore, 1998). White and Mitchelmore (2003) consider that it is clear from the research literature that students have great difficulty in coordinating the various facets of the angle concept. In addition, several authors have observed that students also have different angle conceptions (Mitchelmore & White, 2000).

The process of constructing the concept of angle crosses several obstacles (Mitchelmore, 1998), and the difficulties that students encounter in learning angles and the mistakes made were observed in several experimental studies (Berthelot & Salin, 1996; Mitchelmore, 1998; Mitchelmore & White, 2000; Devichi & Munier, 2013). Berthelot & Salin (1996) report, based on a Close study (1982), that when students have to compare pairs of angles with the same amplitude but with different lengths of sides, many students respond that the larger angle is the one that has one or both sides longer, without taking into consideration the space between them. These studies reveal other misconceptions of some students because they consider that one side of the angle must always be horizontal and the direction of the angular aperture must always be counterclockwise, or that the angle is a sector of a circle.

Students face some difficulties in using a protractor, which have been emphasized in the literature. Sometimes students align the base of the protractor's body along one side of the angle, rather than the protractor's own reference line; or they do not place the origin of the protractor on the vertex of the angle to be measured. They can also read the angle measure clockwise when they should read counterclockwise or vice versa (Tanguay, 2012). Mitchelmore and White (2000) have suggested that the difficulty students have in learning to use a protractor may result from the fact that in a protractor several lines may be chosen for the initial side of an angle but the terminal side must be imagined. On the other hand, the cause of the students' difficulties seems to be the absence of structural angular components, which leads to failure to establish adequate structural mappings.

## Methodology

The present study follows a qualitative interpretive methodology (Bogdan & Biklen, 1997), since it privileges the interpretation of reality according to the perspective of the actors. In total, 171 students who completed the 6<sup>th</sup> grade participated in the study. The selection of these students was intentional and took into account their performance levels. The fact that students expressed different levels of performance permitted us to access a greater diversity of resolution strategies and, consequently, different mental processes and errors. The tasks were solved after the final internal assessment and in school context, which greatly reduces the probability of interfering factors in the study.

The data collection was carried out in a school context between 2012 and 2015 and used: (i) the collection of documents (tasks of NAT and resolutions of these tasks by the students); and (ii) semi-structured interviews to students recorded on video. The interviews were conducted the day after the task was resolved. Each of the students interviewed had the sheet with the resolution produced by them and, after reading each question, explained how they arrived at the answer.

The selection of the 35 students interviewed was made according to the assumptions of the students' selection for the study.

The analysis of the data for this study initially involved the organization of the information obtained by the written productions of the students and the interviews carried out. Secondly, content analysis was used with pre-defined categories: the mental processes used by the students, the difficulties experienced and the mistakes made.

## Results

Of the five tasks of the NAT of the 6th grade between 2010 and 2015, which involve the construction of triangles, two were chosen (one of the test of 2010 and another of 2012). These two tasks have in common the fact that the required final product is the construction of a triangle, but the method of construction of the triangles is different.

### Task 20 of the 2010 NAT

*The perimeter of an equilateral triangle is 18 cm.  
Construct this triangle in the box below. Shows the calculations you make. Make your construction using pencil, ruler and compass. Do not erase the lines that you do with the compass.*

Figure 1. Task 20

In this task (figure 1), students should know that: in an equilateral triangle the length of the three sides is equal; the perimeter must be divided by the number of sides, obtaining the length of each side. After this procedure, the student can construct the equilateral triangle, proceeding as follows: draw a line segment of 6 cm; draw the circumference arcs at a distance of 6 cm from each end of the line segment until they intersect, marking the point of intersection of the two arcs; draw the two line segments that join the ends of the line segment and the point obtained by intercepting the two lines. The student is not required to mark the vertex designation of the triangle.

Of the 171 students who were asked to solve this task, 106 (62%) correctly constructed the triangle. Of these 106 students, 80 (47%) recorded the calculation of the length of the sides of the triangle. The others 26 (15%) did not register the calculations made, as it was requested in the task. However, some of these students wrote 6 cm on the sides of the triangle. Of the 35 students interviewed, all of them performed the division and correctly constructed the requested triangle. Only the student S1 did not construct the triangle with ruler and compass, instead, he used the protractor, as he explains: "First, I divided 18 by 3 and gave me 6. So, since an equilateral triangle has all angles equal to  $60^\circ$ , I drew a 6 cm line segment and placed the protractor here [the student points to the left end of the line segment he drew] and traced an angle of  $60^\circ$ . So I drew a 6 cm line segment. Here [the student points to the other end of the

initial line segment] I did the same thing and joined the line segments.” When asked if instead of constructing the triangle with ruler and protractor using the amplitude of the inner angles could be constructed with ruler and compass, the student replied "Yes." He was also asked why he did not and the student answered: “Because I just remembered this method”.

Of the 65 students who did not answer correctly, 19 (11%) did not register any work. With the exception of S21, these students did not belong to the group of students interviewed and, therefore, it was not possible to know the reason why they did not solve the task. Student S21 justified himself saying that he had no ruler or compass. However, after the interviewer asked him to reread the question, the student explained step-by-step what he should do to solve the task correctly. The interviewer asked why he did not record the calculations to get the length of each side of the triangle and the student replied that he thought he should draw only the triangle. Although this student knew how to solve the first part of the task, for which the drawing material was not necessary, and to be written in the question "Show the calculations you make", did not make any record.

Of the 46 (27%) students who attempted to solve the task, but were unable to construct the requested triangle, 7 recorded the calculations required to obtain the length of each side of the triangle. It seems that these students understand that in an equilateral triangle the length of its three sides is equal and that the perimeter of the triangle is equal to the sum of the length of its sides. However, when they went to construct the triangle they used other lengths. For example, one student used the lengths 6.5 cm, 5.5 cm and 5.5 cm and records 6 cm on each side of the triangle. In this case there seems to have been some problem with measuring the lengths. The line segment measured with the ruler is 6.5 cm and the other two, which were obtained with the opening of the compass, are 5.5 cm. 10 constructed equilateral triangles whose sum of the lengths of the sides is not 18 cm, for example, equilateral triangles with 4.5 cm on each side. Finally, 6 constructed non-equilateral triangles with perimeter of 18 cm. Other constructions were found in which there is no evidence of the use of the compass. In these constructions, it seems to us that students try to construct the triangle with only the ruler. This strategy is used when students cannot remember the method of construction with the ruler and compass.

### Task 12 of the NAT 2012

*Constructs the triangle  $[ABC]$  that obeys the following conditions:*

- $\overline{AB} = 6 \text{ cm}$
- $\hat{BAC} = 30^\circ$
- $\hat{CBA} = 120^\circ$

*Use the appropriate drawing material.*

Figure 2. Task 12

To solve the task 12 (Figure 2), first, students should draw  $[AB]$  and mark points A and B at their ends. Then, with the protractor, they should draw at A an angle of  $30^\circ$  and at B an angle of  $120^\circ$ . When they extend the sides of the angles they find the point of intersection, that is C.

This task was solved by 126 students, having correctly constructed the requested triangle only 40 (32%). Of the other 86 students, 30 (24%) students followed all the steps necessary to construct the triangle, but when they tried to draw the angle of  $120^\circ$  they made incorrectly. For example, student S3 manifested this difficulty, but was able to recognize his own error:

I: Do you think that the measure of this angle is  $120^\circ$ ? [indicating the  $60^\circ$  angle the student had drawn]

S3: No!!

I.: Why?

S3: Because it does not reach  $90^\circ$ . [Marking the sides of an angle with  $90^\circ$  at point B] Because I measured from here to here. [indicating the counterclockwise]

I.: But if angle that is requested is  $120^\circ$ , and is it greater than...?

S3:  $90^\circ$ !

I.: Did not you see that this [the angle of  $60^\circ$  drawn by the student] was less than  $90^\circ$ ? So, how did you draw the  $120^\circ$  angle?

S3: Should start from  $0^\circ$  and count from left to right" [clockwise]

Other type of difficulty in using the protractor was to place the point of reference of the protractor at the point that will be the vertex of the angle and  $0^\circ$  in the extension of the side of the angle. The student S35, after having traced [AB] correctly, cannot explain how to proceed.

I.: The angles of your triangle measure all  $45^\circ$  and the sides measure 6 cm. Here are the arcs made by the compass? Didn't you see the two angles of the triangle in the data?

S35: Yes!

I.: This point marked in the middle of [AB] for what did it serve?

S35: To place the protractor.

I.: And how do you measure the angles from that point?

S35: I didn't know!

Of the 86 students who didn't build the requested triangle, 11 (about 9%) didn't do any work, nor even traced [AB] and 17 (about 13.5%) couldn't geometrically represent the straight segment with the requested measure.

## Discussion

The difficulty in understanding the construction of triangles (on a sheet of paper) begins first by understanding the concept of angle and the concept of measurement, then goes through the use of ruler, compass and transferor, and by understanding its properties. With respect to the first task, a large proportion of the students successfully constructed the triangle. However, the resolution method was not always as expected. A significant number of students find it difficult to use the ruler to draw line segment of a given length. As mentioned by Battista (2007), students who measure the length of an object incorrectly, when one of their ends is not aligned with the zero of the ruler, do not conceptualize clearly how the numerical marks of the ruler indicate the iteration of the length of the unit. Others seem to understand what an equilateral triangle is, but they have been unable to correctly calculate the length of the three sides. We can attribute this difficulty to the fact that some 6<sup>th</sup> graders students still cannot operate the division algorithm or have difficulty calculating mental quotients between integers. Nevertheless, regarding measurement reasoning, and in relation to linear measurement, the majority of the students demonstrated a level of sophistication quite acceptable. However, in relation to the perimeter of a triangle, the level of sophistication of these students is still quite insipient, since a large number of students could not obtain the measure on the side of an equilateral triangle given its perimeter. This would have been the aspect of the task that requires a higher cognitive challenge.

Comparing the results obtained in the first task with the second, we verified that the percentage of students who correctly solved the second one is close to half of the percentage of students who correctly solved the first one. It seems to us that in the case of the second task the construction of an obtuse angle constituted a greater cognitive obstacle to the correct resolution of the task than others detected in the first task. A considerable number of students were not able to draw the angle of  $120^\circ$  correctly. These students have shown difficulties in coordinating the various aspects of the angle concept (White & Micheltmore, 2003), namely they read the angle measurement counterclockwise when it should have been clockwise (Tanguay, 2012). The cause of the students' difficulties seems to be the "absence of adequate structural components" (Mitcheltmore & White, 2000).

There were students who demonstrated difficulty in the conceptualization of angle and in turn in the use of the protractor (Mitcheltmore & White, 2000). These difficulties are manifested in the second step, which is to place the point of reference of the protractor at the point that will be the vertex of the angle and  $0^\circ$  in the extension of the side of the angle. Some students demonstrated this difficulty because they did not know how to place the protractor at the apex of the angle to be measured (Tanguay, 2012). This task required a high cognitive challenge regarding the interpretation of the question, in part because of the symbolic mathematical load that is presented to students.

## Conclusions

The results evidence that, in linear measurement, many students demonstrated a level of sophistication quite acceptable. They confirm that young students can determine lengths and use correctly material (Joram, Subrahmanyam, & Gelman, 1998), namely developing measurement reasoning (Battista, 2007). However, different difficulties may arise in the construction of triangles (Zamagni & Crespo, 2016), namely due to the absence of adequate structural components. Students' difficulties in the conceptualization of measurement and angle were obstacle to the understanding and resolution of the tasks. Additionally, students have difficulty in decoding and transforming mathematical information. The combination and coordination of motor and visual skills in the use of didactic materials is very relevant in solving tasks of triangles on paper, and for this reason the knowledge of the properties of the triangles and the consolidated knowledge of the concept of measurement and of angle are essential.

<sup>2</sup>Leipzig University, Leipzig, Germany; [simone.reinhold@uni-leipzig.de](mailto:simone.reinhold@uni-leipzig.de)

*Our paper presents early findings from a study that investigated Australian Grade 3 and 4 students' geometrical conceptual knowledge. This study is part of an international collaboration between Australian and German researchers. It draws on earlier research of Year 3 German students' cube constructions, errors and misconceptions and the categorization of these. The student data reported in this paper was analyzed using a framework for guiding and describing sources of errors and/or misconceptions related to cube constructions. These findings highlight the importance for students to construct three-dimensional objects using a variety of materials.*

*Keywords: Geometrical concept knowledge, cube constructions, primary students, errors.*

### Introduction

Research relating to children's geometric reasoning has focused on the classification of geometric objects and application of the Van Hiele levels of geometric thinking (Bleeker, Stols & Putten, 2013). Within the early years of primary school, less has been reported on children's knowledge and visualization of three-dimensional objects, in detail. There is also limited Australian research of young children's knowledge of geometry (MacDonald, Goff, Docket & Perry, 2016).

Our research is an international collaboration between German and Australian colleagues, and in this paper we report Australian data collected from Grades 3 and 4 students. Our objective was to investigate whether students' constructions of three-dimensional objects (e.g. prisms) elicits insights into their understanding of the properties of prisms that would not otherwise be revealed. In the German iteration students responded to a one-on-one task based interview using Froebel's Gifts, small wooden blocks (cubes and prisms). These blocks are not commonly used in Australian schools and we were interested in how Australian students might demonstrate their geometrical conceptual knowledge when using Froebel's Gifts to construct larger prisms.

Geometrical conceptual knowledge refers to students' spatial concepts, including visualization, verbal, and construction skills, their understanding of the relationships between two-dimensional shapes (2-D) and three-dimensional (3-D) objects, and their reasoning processes (e.g., Dindyal, 2015). In this study, geometrical conceptual knowledge referred to students' perceptions, visualization skills and identification of distinct properties of 3-D objects, in particular prisms, prior to and when constructing different sized cubes.

Prior to this collaboration, the third author used Froebel's Gifts and construction tasks to investigate Grade 3 German students' knowledge of geometrical solids (Reinhold & Wöller, 2016). Students' construction strategies and products were interpreted according to the Van Hiele framework. The

results indicated a wide variety of students' geometric conceptual knowledge of solids. Further studies of Grade 3 and 4 students' understanding of geometrical objects, including Australian students, would provide further insights of students' conceptual knowledge of 3-D objects, and into common errors or (mis)conceptions that might occur. Ulusoy (2015) suggested a model that identified a wide variety of selection types and errors relating to the identification of 2-D shapes (trapezoids). Our pilot study builds on other studies such as Fujita, Kondo, Kumakura and Kumakura (2017) who described older students' errors in relation to cube representations, and Finesilver (2016), who examined the spatial structuring, enumeration and errors of students working with 3-D arrays. Informed by these previous studies, these research questions guided our study:

- What errors are identified when Australian Grade 3/4 students use small cubes and rectangular prisms to construct cubes?
- What codes and categories can be used to classify students' responses and sources of errors and/or misconceptions when constructing cubes?

## **Theoretical framework**

The initial framework that guided our analysis was developed in a previous study (Reinhold & Wöller, 2016). However, an in-depth analysis of the Australian data necessitated a widening of the initial framework. This also included drawing on the works of scholars who investigated children's errors of cube constructions, providing an opportunity to investigate further insights into children's geometrical conceptual knowledge through the lens of the students' errors.

### **Cubes and cube constructions: revisiting the Piagetian framework**

The Swiss psychologist Piaget is well known for his contributions to children's cognitive development, including a framework of their intellectual development. According to Piaget and his colleagues, young children begin to understand space by exploring simple relationships such as order and enclosure, separation and proximity. This encompasses an understanding of topological relationships – which is ensued by the development of understanding projective and Euclidian concepts of space (Piaget & Inhelder, 1967). Euclidean concept of space, objects (or parts of them) are located not only relative to each other, but also according to co-ordinate axes in 3-D space. These three dimensions and relationships determine an understanding of a cube as one of the five Platonic solids. A cube is classified as a 3-D object comprising 12 edges of equal length, 6 square faces with 3 faces meeting at each of the 8 vertices. In terms of class inclusion, the cube is the only regular hexahedron, and differs from other rectangular prisms because it can be classified as a regular square prism (all rectangular faces are squares).

Children's cube constructions, in particular their errors and strategies when copying (cube) buildings have been investigated from the 1920s onwards (Reinhold, 2007). For example, Piaget and Inhelder (1971) investigated how children copied cube constructions (consisting of seven or more single cubes, displayed on a picture or as a solid model) when using wooden cubes. The analysis of these studies by Piaget and Inhelder included a classification of children's errors. For example, young children may identify units of a construction, but assemble them incorrectly (wrong orientation of segments in the construction). Furthermore, a global similarity of the cube construction may stand in contrast to incorrect details (e.g., wrong number of cubes). These observations are in

line with Piaget's overall notion that young children focus on single aspects of a phenomenon and prevents them from simultaneously taking various viewpoints into account and relates to their struggle when coordinating different perspectives of 3-D objects.

### **Visualization, coordination and integration of views in cube construction**

Recent studies have also explored the notion of children's inability to coordinate and integrate their ideas simultaneously in visualization tasks. For example, Reinhold (2007) found that children tended to focus on isolated features, as they visualize "in bits" rather than sequentially when doing mental rotation tasks that included cube constructions. Instead of visualizing the entire structure of a construction, students were more likely to take into account only small portions of a 3-D array in an additive manner. Gorgorió (1998) found that focusing on single elements of a construction appears to happen more frequently when students construct by themselves, in contrast to drawing their responses.

Battista and Clements (1996) reported students' inability to coordinate two different orthogonal views for the construction of a rectangular prism when counting the number of single cubes. They found a lack of coordination whenever the students were unable "to recognize how they [the orthogonal views of a prism] should be placed in proper position relative to each other" (p. 267). This prevented some students from forming "one integrated mental image of the objects" (p. 272). Students' initial conceptions of rectangular prisms were characterized as uncoordinated sets of faces, and in transition to a more elaborated understanding, students may then reconstruct in layers, yet focus locally, piece by piece. Battista & Clements also argued that in order to enumerate the number of cubes students must have a mental model of the prism, and that spatial structuring provides the input and organization for enumeration. They defined spatial structuring as:

the mental act of structuring an organization or form for an object or set of objects. The process ... includes establishing units, establishing relationships between units ... and recognizing that a subset of the objects, if repeated properly, can generate the whole set (the repeating subset forming a composite unit) (p. 282).

### **Understanding of class inclusion in the Van Hiele framework**

The *development of geometrical conceptual knowledge* from primary to secondary school has been defined as five levels of development (Van Hiele, 1986). According to Van Hiele (1986), younger children identify shapes by recognizing resemblances to everyday objects or by identifying prototypes in the stage of *Visualization*. In the ensuing stage of *Analysis* they are more likely to take a shape's properties into account when they decide upon categorization. Battista (2007) suggested renaming the *Analysis* stage as 'Analytical/Componential' which encompasses three stages. The first is the "visual-informal componential reasoning" stage in which students focus on parts of shapes and then on the spatial relationships between the parts using visually based descriptions, that utilize informal language. In the next stage, "informal and insufficient-formal componential reasoning" their descriptions are a combination of informal and formal language, whereas in the final stage, "sufficient formal property-based reasoning" they use formal geometric language when describing and conceptualizing shapes. Students who have not reached the stage of *Analysis*, as defined by the Van Hiele, are unable to give a concise definition of a geometrical object whilst taking account of

mathematical properties (Reinhold & Wöller, 2016). When students begin debating about the impact of various properties of relationships between shapes, they achieve the stage of *Abstraction*.

## Method

We report three case studies that were representative of the Australian cohort in relation to the errors identified from the analysis that investigated Grade 3 and 4 students' (N=24) understanding of geometric objects whilst constructing a "cube". Students responded to a one-to-one interview (designed by German colleagues) using Froebel's cubes and cuboids (rectangular prisms) (see Figures 1-3), identifying insights into their understanding of the properties of prisms. Each interview was conducted by the Australian authors and video-recorded for later analysis. Students were asked to construct different cubes using smaller cubes (Froebel's Gift # 3) and then using rectangular prisms (Froebel's Gift # 4) (Reinhold, Downton & Livy, 2017). Examples of questions asked during interview included:

"Close your eyes and imagine a cube. Describe what you see."

"I want you to build a cube using these blocks (2cm cubes). How do you know this is a cube?"

"Can you build a different cube? How do you know this is a cube?"

"I want you to build a cube using these blocks (small rectangular prisms) ..."

"Compare this cube (one 2 cm cube) with this rectangular prism (small rectangular prism).

"How are they the same and different? (blocks shown to student)"

Following an interpretative paradigm in qualitative data analysis, we used student responses and performance data for the analysis, guided by *Grounded Theory* methods (Corbin & Strauss, 2015). The first two authors independently used open coding, while viewing the videos, identifying key themes related to their responses and to their construction process. We highlighted evidence of students' difficulties with their visualization skills as well as when students mentally structured solids or assembled parts of their constructions. Three case studies are presented to show examples of the following coding and categories:

*COORDINATION & INTEGRATION* is evident when students notice the properties of the solid they are constructing including an ability to coordinate distinct units of (visual or cognitive) information, and simultaneously integrate all spatial information (spatial relationships and properties). Whenever some of these properties are not yet fully developed, the students focus on isolated units of visual or cognitive information. Elements of this category and visualisation encompass spatial structuring (Battista, 2007).

*VISUALIZATION* includes cognitive processes related to visual perception, mental images and mental transformation of the entire cube or of smaller units. This may challenge students' ability to see and imagine spatial relationships and the representations of a cube or parts of the object (e.g., mentally rotate or (dis)assemble parts of the cube that is under construction).

*CLASS INCLUSION* refers to knowledge of the relationships between two solids (e.g., cube as a special rectangular prism) and students' understanding the structure of the hierarchical classification. In single cases, this may include the use of terms indicating class inclusion (e.g., prism, rectangular prism, rectangular square prism). Similarly, when describing a cube, the three students related their

description to everyday objects, such as, *it's like a box, a yellow block*, which is evidence of Level 1, Visualisation (Van Hiele, 1986).

*FLEXIBILITY* consists of students' ability to visualize and construct more than a single appropriate representation of a cube ( $2 \times 2 \times 2$  as most common prototype). This may also address the idea to mentally (dis)assemble their own construction in various ways in order to flexibly find more than one solution (e.g., to enlarge a cube in length, width and height by adding one block). Whereas *STABILITY* refers to having a strong (mental) image of an object.

These categories prompted a critical debate allowing us to consider further interpretations for classifying and discussing students' sources of errors.

## Results

The results focus on selected examples of three students' errors and (mis)conceptions showing screenshots to support our findings. We grouped and categorized their errors and (mis)conceptions, providing examples of each category (described above and in Figure 4).

### Edward (pseudonyms used throughout) (aged 10 in Grade 4)

When asked to describe a cube Edward said, "A cube has 8 corners and 12 edges and is 3-D." He was able to construct a  $2 \times 2 \times 2$  cube (length x width x height) using eight smaller cubes and said, "It is equal on all sides and is 3-D". For his second cube construction, he built a  $3 \times 3 \times 3$  cube using 27 cubes stating, "All faces are equal." However, when asked to construct a cube using small rectangular prisms Edward did not draw on this insight. After an attempt to construct a cube using six rectangular prisms (see Figure 1 left), he removed two blocks (top layer) leaving a  $2 \times 2 \times 2$  construction (Figure 1 middle). He said, "This is now a cube." Edward was focusing incorrectly on the dimensions of the object ( $2 \times 2 \times 2$ ) rather than the properties of a cube that all faces are equal. Next, he incorrectly constructed another cube (Figure 1 right) he responded that it was a cube because, "All the faces were even," revealing another misconception. Edward's construction of a cube using cubes was the 'prototypical' cube and he recognised that all the faces were equal. This response also aligns with his initial answer to the first interview question, in which he said, "a cube has six faces that are all equal and it looks like a dice". When challenged to construct different cubes using rectangular prisms he struggled. When asked why the third construction was a cube he indicated that all faces are even. It is possible that he was attending to the top face (a square) and did not notice that the other faces were rectangles.

**Figure 1: Edwards' response when making cubes with smaller rectangular prisms.**

### Emma (aged 8 in Grade 3)

When asked to describe a cube Emma said, "It is a yellow block and it has 8 points and 6 sides and [...] is a 3-D square." Emma referred to a cube as a 3-D square and attended to a holistic

appearance (Van Hiele, 1986). With smaller cubes, she constructed a  $2 \times 2 \times 2$  cube by using a strategy of trial and error. Again, she said, “It is a cube because it is a 3-D square (counting the edges twice) with 8 points (counting the faces) and 6 sides.” When using the smaller rectangular prisms (Figure 2 left) she struggled and said, “I know it’s not a cube, it’s a rectangle but I don’t know how to make it a cube from here.” After several attempts (Figure 2 right) Emma concluded that she could not construct a cube. Emma had difficulty visualizing and constructing a cube when using rectangular prisms, most likely attributed by her lack of experiences with these blocks.

**Figure 2: Emma’s response when making cubes with smaller rectangular prisms.**

### **Chloe (aged 8 in Grade 3)**

When asked to describe a cube, Chloe said, “A cube is like a box ... it has 12 faces ... is a square shape.” Chloe had difficulty constructing cubes (using cubes) and attempted to build an outline of the base of a cube ( $5+5+5+4$ ) (Figure 3 left). Next, she built “towers” four cubes high on each corner (Figure 3 second) and filled in the ‘walls’ (Figure 3 third). Chloe said, “This is not a real cube because it needs to be filled up,” nor did she recognize the faces were not equivalent. Her final incorrect cube construction (Figure 3 fourth) had an uneven frame ( $5+5+6+4$ ). After several attempts of counting the cubes Chloe still could not identify her error or make each length of the ‘faces’ equal. Her error related to spatial structuring when counting single elements (“Four, four, four and four.”) in a cube construction (Figure 3 right, the arrow visualizes her starting point for counting).

**Figure 3: Chloe’s single steps when making a cube with smaller cubes and her counting of each cube.**

The results of these case studies highlight the following (mis)conceptions or errors:

- Attention to the dimensions rather than properties of a cube (when using rectangular prisms)
- A focus on the top face being square (rather than all faces being square)
- An inability to visualize and construct a cube (when using cubes and/or rectangular prisms)

Our results confirm those of Reinhold (2007), that students tend to visualize “in bits” rather than visualizing the entire constructions, and their lack of spatial structuring (Battista, 2007), when constructing cubes. Many of these misconceptions or limited conceptual knowledge were evidence of: *co-ordination* and *integration*, *visualization*, *class inclusion* and/or *flexibility* and *stability* (Figure 4).

## Discussion

The following discussion includes the results in relation to the four categories shown in Figure 4. Doing so highlights the cognitive demands and developmental aspects that we identified as possibly influencing the variety of students' correct solutions (not reported within this paper) and errors. As indicated in the literature, these categories were not entirely new to this field of research. Each of the four cases revealed difficulties in one or more of these categories.

**Figure 4: Sources of errors in Grade 3/4 students' concepts of cubes.**

**COORDINATION & INTEGRATION:** Edward focused on the dimensions of the constructions rather than the properties of a cube when constructing a cube using rectangular prisms. He was focusing on isolated bits of information and units when visualising (Figure 1). **VISUALIZATION:** Emma and Chloe had difficulties with their spatial structuring when visualizing and making a cube using smaller rectangular prisms (Figures 2 & 3). They were unable to see and imagine spatial relationships and the representations of a cube or parts of the object (e.g., mentally rotate or (dis)assemble parts of the cube that is under construction). **CLASS INCLUSION:** Students such as Edward had not yet developed class inclusion as they could not conceptualize that a cube could also be classified as a rectangular prism. **FLEXIBILITY:** Most students in our study require further development of their understanding of the properties of cubes and rectangular prisms in order to develop *flexibility and stability*.

## Conclusion and Implications

A commonality across the results was students' inability to integrate all spatial information simultaneously (e.g., Battista & Clements, 1996; Reinhold, 2007) and their lack of spatial structuring. Many students within this study could state properties of a cube correctly ("6 faces, 8 vertices and 12 edges") yet further exploration of their ability to construct and classify geometric objects revealed lack of spatial structuring. For instance, some students struggled with the idea that two adjacent cubes formed a rectangular prism (mental transformation referring to visualization). Hence, we argue that a deep understanding of the concept of a "cube" is not entirely developed until a student has the capability to *coordinate and integrate*; consider *class inclusion* correctly; *visualize representations* of a cube or parts of an object; and to find an appropriate balance of *flexibility and stability*.

These insights into student errors and/or misconceptions has highlighted the need to provide students with many opportunities to construct cubes (and cuboids) beyond the prototypical using a range of materials. An implication of our study is to highlight the importance for (Australian) teachers to use construction tasks to develop students' geometric thinking related to three-dimensional objects. Ongoing in-depth analysis of individual students' geometrical concepts of rectangular prisms aims to strengthen these findings and provide opportunities for further research.

# TWG05: Probability and Statistics Education

## Introduction to the work of TWG5: Probability and Statistics Education

### Leaders:

- *Caterina Primi (Italy)*
- *Aisling Leavy (Ireland)*

### Co-leaders:

- *Pedro Arteaga (Spain)*
- *Daniel Frischemeier (Germany)*
- *Orlando Rafael Gonzalez (Thailand)*
- *Sibel Kazak (Turkey)*

### Introduction

The working group gathered 42 participants from 20 countries. 27 papers and 9 posters were accepted. In the first session after the organising team presentation we explained the three Cs of CERME, introduced the aims of the conference and of our TWG. In order to create a collaborative atmosphere, that would support the discussions and feedback over the following days, we started with an ice-breaker activity involving all the participants in a “Bingo” game”. Through this activity participants got to know their TG5 colleagues in a low stakes and collaborative context. Following this, the participants were asked to introduce themselves and their expectations for the working group and the conference. Among the expectations communicated were: to receive constructive feedback on their work, to gather new ideas, to get informed and updated on new trends in statistics and probability education, to get better acquainted with emerging research from other countries and develop possible collaborations and networking opportunities.

Participants were introduced to the three subthemes identified as emerging across all submissions. In particular, submissions focused on “Teacher education”, “Reasoning about data” and “Statistical and Probabilistic Thinking and Reasoning”. However, we remarked that there was some overlap and similarities across subthemes: submissions on Teacher education also focus on subtheme 2 (Reasoning about data) or on subtheme 3 (Statistical and Probabilistic Thinking and Reasoning). Additionally subthemes 2 and 3 are not seen in a disjoint way – which means, in both subthemes 2 and 3 we can of course also find submissions with connections between the “data world” and the “probability world”. Following this, participants were split into groups and each group discussed these subthemes. As part of these discussions, the co-leaders introduced and discussed several questions for the discussion in all subthemes during the sessions across the days to follow:

- What experiences can we provide to promote and develop learners understanding when reasoning about data / Statistical and Probabilistic Thinking and Reasoning?
- Which (typical) (mis-)conceptions of learners can be identified when reasoning about data / Statistical and Probabilistic Thinking and Reasoning?

- How should tasks and learning environments be designed to enhance reasoning about data / Statistical and Probabilistic Thinking and Reasoning for learners (primary students, high school students, teachers, etc.)?
- Which research methods are used / should be used to find about students' or learners' reasoning with data / Statistical and Probabilistic Thinking and Reasoning?
- How and in which way can we build bridges between data analysis, probability, and inference? Which role does context play?
- How and in which ways can the use of digital tools enhance statistical reasoning (reasoning about data and statistical and probability reasoning)?
- What about the handling of Big Data in the upcoming Data Science era? How can we (statistics education) profit from the availability of Big and Open Data? Which implications does it have for statistics education?

For all the sessions during the week the participants were split in two groups: TWG5a with Caterina Primi (Leader) and Sibel Kazak and Orlando Rafael Gonzalez (Coleaders) and TWG5b with Aisling Leavy (Leader) and Daniel Frischemeier and Pedro Arteaga (Coleaders). For each subtheme we organized two sessions managed and chaired by one of the co-leaders. We also organized a poster session with all participants (both groups together) where each presenter had 5 minutes to present the poster and the rest of the session had time allocated for the discussion.

The last day we had a culminating session with all participants with the aim being to engage in an in-depth discussion on subthemes and to share the contributions discussed during each session.

### **Teacher education**

From the discussions of various papers addressing pre- and in-service teacher education in our working group, the following ideas and implications emerged, regarding how to prepare teachers to address and foster students' reasoning and thinking about statistics and probability:

- to enhance the pedagogical content knowledge facets of statistical knowledge for teaching, and not just focus on the subject matter knowledge facets;
- to make teachers familiar with performing statistical tasks and investigations from a procedural, interpretative and contextual perspective, while making connections among fundamental ideas of statistics (e.g., data and randomness), chance, relevant and appealing real-life contexts, software and technology;
- to include childhood statistical ideas (both formal and informal) in early years education, and prepare teachers to address and foster them;
- to create Professional Learning Communities (i.e., communities of practice within schools and beyond);
- to consider the affordances of games, university entrance examination tasks, and real-life problem scenarios as triggers for engaging students in high-quality statistical investigations, grounded on production tasks (as opposed to judgement tasks);

- to develop teachers' statistical reasoning and thinking by engaging them in the interpretation, design, teaching and assessment of stochastic tasks and statistical investigations organized around the three stages of teaching (i.e., lesson design, classroom implementation and reflection);
- to develop teachers' assessment skills regarding the most suitable strategies to assess students' statistical reasoning and thinking, in terms of their effectiveness (e.g. peer review among students, projects, written reports);
- to raise pre- and in-service teachers' awareness of the importance of providing interdisciplinary experiences to learn statistics (e.g., STEAM);
- to raise pre-and in-service teachers' awareness of the importance of providing students with opportunities to work with big data and personalized data; and
- to employ qualitative approach (e.g., observations, interviews, analysis of artefacts and final reports), action research, statistical argumentation, and analysis of statistics within social issues as methods to explore teachers statistical and probabilistic knowledge, thinking and reasoning.

### **Reasoning about data**

From the discussions of various papers focusing on the reasoning about data, the following ideas and implications emerged in our working group:

- The Data Science era is emerging: Data are everywhere and the exploration and analysis of Big data and Open data will be a fundamental aspect in reasoning about data. Furthermore, there are other data collection methods which become more relevant (e.g., with Sensors, web scraping, etc.) and which provide new types of data.
- The necessity to cooperate with other disciplines like computer science, social science and citizen science is becoming increasingly evident. Especially for Data Science, collaboration with computer science is inevitable.
- The use of digital tools when exploring data is fundamental. We need to both consider and make the distinction between educational software tools (like TinkerPlots or Fathom) and professional software tools (like R, Python). Also open source and online tools like Gapminder and CODAP can help develop reasoning about data.
- Data competence has to be developed continuously from primary school to adult education. Especially in primary school, data competence and more specifically reasoning about distributions can be enhanced by using pre-formal concepts like modal clumps which offer a pre-stage for the concepts center and spread for example.
- The facets data, chance and context are tied strongly together.

### **Statistical and Probabilistic Thinking and Reasoning**

From the discussions of various papers focusing on the statistical and probabilistic thinking and reasoning, the following ideas and implications emerged in our working group:

- The use of context, real problems and visualization tools can support statistical and probabilistic thinking and reasoning in data and chance explorations.

- The focus on interpretation and justification of results is essential to promote statistical and probabilistic thinking and reasoning.
- Studies suggest that building on learners' intuitions and emerging conceptions, rather than focusing on their misconceptions, becomes more useful for supporting their thinking and reasoning in data and chance.
- The use of real or realistic data can motivate learners to use statistical and probabilistic ideas in their thinking and reasoning.
- To move the field forward considering design based research as an additional methodology can inform how to build statistics learning environments that support learners' statistical and probabilistic thinking and reasoning.

## Conclusion

The field of statistics and probability education is a fast evolving area and to draw on the words of H.G Wells (cited in Huff, 1954) 'Statistical thinking will one day be as necessary for efficient citizenship as the ability to read and write'. As such, we identified several critical areas of focus for research and practice in statistics and probability education. Firstly, gaining access to the 'big ideas' in statistics and probability is important for effective citizenship. Exposing young children, in the early primary years, to informal ideas of statistics and probability is a critical step in order to develop and lay the foundation upon which formal understandings will be built upon. Related to this is the second recommendation that we establish a trajectory of learning experiences to support the continuous development of statistical and probabilistic reasoning and thinking from early years to adulthood. A guiding signpost for both educators and researchers alike, is provided in the third suggestion, and that is to maintain the important connection between data, chance and context as we move forward in the field. Two emerging areas to keep abreast of as we make advancements are the need to be prepared for Data Science (the implementation of Big Data) and its' implications and also to continue to develop and makes use of appropriate digital tools ( such as Gapminder, CODAP, TinkerPlots, Fathom etc.). Finally, we conclude with a reminder to remain mindful of the need to diversify our research design and approaches to inquiry - incorporating attention to fine-grained studies, eye-tracking research, larger cross-comparative studies, experimental design, to name but a few – all in an effort to advance our understandings of the complex and evolving areas of statistics and probability education.

## Formalizing students' informal statistical reasoning on real data: Using Gapminder to follow the cycle of inquiry and visual analyses

*Graphical representations of Open Data facilitate students' personal engagement in discovering and exploring data and enable students to intuitively access certain statistical concepts. The aim of this study is to identify important patterns and fundamental limitations in the learning processes when students acquire deeper understanding of "big ideas of statistics" (Garfield & Ben-Zvi, 2008). The objective of the study is to nurture students' intuitive knowledge (Fischbein, 1987) by using the software Gapminder for data visualization in classrooms. In this exploratory study 19 students aged 14-15 were guided through two lessons of 1 hour and 40 minutes, each, using the Gapminder tool and materials to explore and visualize sets of Open Data while working on several worksheets and test items developed by the research team. Findings of this initial study are being used to further conceptualize and design successive investigations.*

*Keywords: Statistics education, statistical literacy, visual data analysis, statistical reasoning, intuitions.*

### Theoretical background

This study is primarily based upon the cycle of inquiry and visual analysis (Prodromou, 2014), complemented by works on students' statistical literacy (Prodromou & Dunne, 2017), their development of the big ideas of statistics (Garfield & Ben-Zvi, 2008) and various research studies on the use of technology in the era of Open Data with a special focus on the visualization of context-based data. Acknowledging that graphical representations play a fundamental role in intuitively understanding of abstract mathematical or scientific concepts (Fischbein, 1987), theories on intuition (Fischbein, 1987), heuristics and biases (Tversky & Kahnemann, 1974) are considered.

Tversky and Kahnemann (1974), Fischbein (1987) stress the influence of connate heuristics, biases and misconceptions on making decisions or judgements under uncertainty (Tversky & Kahnemann, 1974). Studies have examined specific heuristics, biases and misconceptions within the learning processes of statistics and probability theory (Garfield & Ben-Zvi, 2008). Thus, it is a central challenge in statistics education, to address students' intuitions in order to identify their biases and misconceptions and support students to overcome their misconceptions. In fact, misconceptions are strongly bound to context because students think differently about stochastic concepts in various contexts.

Makar et al. (2011), as well as other researchers in Statistics Education, emphasize the importance of context and the use of real data in statistical reasoning. Ben-Zvi and Aridor-Berger (2016) demonstrate students' transition between context and data and also report on students' growing understanding of the ways to combine these contexts and data. Although there is little research on the

question what makes data “real”, we can presume that students perceive data to be real when they get personally affected by the data. Therefore, Open Data on topics of general interest may be considered as real data easily accessible for teachers and students.

Advances of new technology with numerous opportunities for data visualization prompted Prodromou and Dunne (2017) to argue for the profound importance of using Open Data in statistics education. Analyzing Open Data with the software TinkerPlots in classroom, Watson (2017) describes the chances of learning statistics in a transdisciplinary way, integrating statistics education in non-mathematical topics, such as to Health and Physical Education, Social Science or History.

Garfield and Ben-Zvi (2008) outline various research studies on students’ development of different big ideas of statistics, which they identified as crucial for statistical reasoning: a) *data*, including the nature of data and the diverse types and sources of data b) *statistical models*, such as regression and the Normal Distribution as statistical models, c) *distribution*, involving the ideas of shape, centre and spread, d) *centre*, covering the difference between median and mean, e) *variability*, including the measuring of the spread of a distribution, f) *comparing groups* by centre and spread, g) *sampling*, containing, e.g., the effect of sample size, h) *statistical inference* as to testing hypotheses or confidence intervals, and i) *covariation* with scatterplots, correlation and linear regression. The theory-based recommendations given with the presented activities for the development of the big ideas of statistics comprise learning these ideas explicitly, addressed in a constructive way and facilitated by examining real data sets. Furthermore, Garfield and Ben-Zvi (2008) also suggest learning the big ideas of statistics beginning with students’ intuitions and preconceptions, taking their informal notions of the single ideas and turning them into formal notions. Teaching must start with introducing students’ intuitions and preconceptions, identifying intuitions and preconceptions and rectifying them using different techniques including the use of digital technologies and graphical representations of data to display the summaries and visualizations of data.

Visualizing data is one of the most intuitive ways of understanding underlying concepts from data and “graphical excellence is that which gives to the viewer the greatest number of ideas in the shortest time with the least ink in the smallest space.” (Tufte, 1983, p. 51). Moreover, presenting information with diverse graphical representations is a highly important skill for many scientific disciplines aiming to make data meaningful (Tufte, 1983). Therefore, new types and the diversity of data in our age also require new ways of structuring, organizing, and visualizing data. Traditional, static visualization techniques such as bar charts, boxplots or distributions for single variables often fail to meet requirements of current data sources and analyses. Thus, processing and visualizing data with new techniques using specific, sophisticated technology plays an important role in students’ developing understanding of statistics.

Using TinkerPlots for exploratory data analysis in the classroom, Ben-Zvi and Ben-Arush (2014) focus on the instrumentation process of transforming an artifact (i.e., a software with no meaning for the students) into an instrument (i.e., a tool, that is meaningful and useful to the learners). Based upon their observations, the authors suggest three types of instrumentation processes: a) *unsystematic*: students playing and experimenting with the software in a non-intentional way, b) *systematic*:

students being focussed on the tool rather than on the task, but applying the software purposefully, and c) *expanding*: students using the software fluently and focussing on the task.

Prodromou (2014) presents a project concluding that the students were able to flexibly use the software Gapminder to build visual structures that highlight information relevant to their analysis task. In addition, various studies concerned with the implementation of Open Data in school education (e.g., in Prodromou, 2017; Engel et al., 2016) and the technologies used for this purpose (e.g., Forbes et al., 2014) show promising possibilities to beneficially integrate Open Data in statistic courses by operating with visual methods.

To meet the needs of exploring and analysing data particularly by visual methods, Prodromou (2014) presents the cycle of inquiry and visual analysis, especially elaborated for that purpose. The steps of this cycle are: a) identifying the task, b) foraging for data, c) searching for visual structure and implementing visualizations, d) developing insight through interaction with the resulting data visualizations, and e) acting with regards to work further on any step to develop deeper insight or ending the cycle. All these stages are connected to each other and the process of visual analysis includes continuous interactions between the stages. Furthermore, basic statistical literacy is a prior condition for exploring data by visual methods, being deepened with these investigative processes. Therefore, Prodromou and Dunne (2017) have introduced a framework for constructing statistical literacy in schools, incorporating new possibilities arising in the age of Open Data and strongly bound to the diverse graphical representations of data.

In the teaching of basic statistics courses, students' intuitions and preconceptions have to be addressed and we also need to consider their biases and misconceptions. Working with graphical representations assists students to access their *intuitive knowledge* (Fischbein, 1987). According to researchers (e.g., Makar & Ben-Zvi, 2011), it is crucial to work with context-based data that are meaningful and important for students. Thus, meaningful data-processing needs visualizing real data, includes entire cycles of inquiry, and particularly addresses the *big ideas of statistics* (Garfield & Ben-Zvi, 2008). Furthermore, an updated concept of statistical literacy required for our age of data society (Prodromou & Dunne, 2017) should address students' perceptions and assessment of large sets of data. Finally, using technology autonomously and fluently, allowing focus on the task rather than on the software, is a fundamental factor of students' constructing their statistical knowledge and skills (Ben-Zvi & Ben-Arush, 2014). Therefore, the aim of this study is to develop new ways of teaching basic statistics, integrating students' intuitions addressed by the visualizations of Open Data with the software Gapminder. In our exploratory pilot study, we aimed at identifying important patterns and fundamental limitations regarding students' intuitions on statistical concepts, their statistical literacy, and their instrumentation processes to further conceptualize this investigation.

## Methodology and implementation

The present pilot study is embedded in a larger study investigating students evolve their intuitions and preconceptions from informal perceptions of statistical concepts to a higher and more formal level by using different visualization tools. The research question concerning the present study is: How do activities related to analyzing real data by visual methods contribute to formalize students' statistical reasoning? The entire study follows the methodology of design-based research (Cobb et

al., 2003), utilizing an iterative design of the implementation of a learning environment and approach based on analysis of variety of data sources at the subsequent stages. We analyze students' conceptualization of the *big ideas of statistics* inherent in the applied worksheets and tests while examining data with the software Gapminder. The worksheets were used to get a broad range of tasks and corresponding answers; the test items included both closed and open-ended questions. Results of the worksheets and tests were anonymized during transcription and translation by using pseudonyms. Transcripts were analyzed qualitatively using MAXQDA qualitative analytics software by categorizing the answers in response to various statistical ideas addressed. Although it was planned to visit classes and conduct interviews with students, researchers were not allowed to collect any additional data from students beyond the worksheets and tests. But, interviews with the teacher before and after the lessons offered further information on the circumstances and settings of lessons and insights into students' work.

In total, 19 students in the 8<sup>th</sup> grade participated in the study. They had not worked with the software Gapminder previously nor had they received any prior instruction on distributions and variability in their school. However, their pre-knowledge, which could have an influence on solving tasks, includes calculating the mean and graphical representations of functional relationships in non-statistical, linear contents. The participating teacher was introduced by the researcher to the software and the instructional items of the study. Learning activities took place in a computer lab with a PC for each student and had duration of one week with two lessons of 1 hour and 40 minutes. The topic of the lessons was to find out more about poverty in the world.

Using two worksheets, the first lesson aimed at introducing students to the software as well as to ideas of investigating and exploring data sets. In the second lesson, using a third worksheet, students were asked to explore autonomously visualisations of various datasets. Between the different learning sequences, some test items were introduced to find out more about the students' statistical preconceptions and the conceptions they gained. The test questions were partly open-ended and partly closed, a structure familiar to the students from Austrian national standardized tests. The content of the first worksheet is about eight sets of interactive slides on human development trends, provided by the Gapminder foundation as instructional material (<https://www.gapminder.org/downloads/human-development-trends-2005/>). These slides show different visualisations (see figure 3) of the variables

**Figure 1: Visualizations of income distributions used in the first test**

*income* and *child mortality rate (health)*. Visualisations explained and described the distribution of income of all countries in the world and the relationship between *income* and *health* over time. This worksheet contains questions on statistical ideas that address central value, variety, distribution's shape, and correlation between variables based on the topic. As the tasks were open-ended and students did not get any instruction before, they were required to describe their ideas on the tasks intuitively. Connected to the first worksheet, the first test items were developed to directly address the students' intuitions of centre, distribution, and variability by giving them two diagrams of different income distributions (see figure 1). The students were asked to reason about the shape of the second distribution and to compare it to the first distribution regarding the centres of these distributions. Additionally, students were asked to explain why the median income in 2015 most probably belongs to a person from a middle-income country and to describe the income of Chinese people in 1987 (light green top of the left peak). The second worksheet was a step-by-step guideline to follow the cycle of visual analysis (Prodromou, 2014) with different variables using the Gapminder software. There was no data collected on this second worksheet. The third worksheet contained some general instructions and suggestions, which variables the students may use for their autonomous investigation of the topic, e.g., income and literacy rate. The students participating were asked to document the findings of their investigations.

A second test, held at the end of the second lesson, included questions on a bubble chart (see figure 2) showing the variables *income* and *sanitation*. The focus of the test was on the ideas of correlation, centre and distribution. Students were asked to describe the bubble chart depending on the income levels and got a set of five statements addressing the various statistical concepts (e.g., variety, centre, or spread) to choose the right ones. With exception of the investigational learning sequences, the students were asked to work independently. The teacher supported the students' learning process by assisting them while working with the software and the topic. When the students solved the tests independently, they did not receive any assistance.

**Figure 2: Bubble chart of the variables income and access to improved sanitation used in the second test**

## Initial results and discussion

In this section we present and discuss some of the main results of the pilot study to pinpoint directions for further investigation. Results presented focus on some of the *big ideas of statistics* (Garfield & Ben-Zvi, 2008) connected to the students' intuitive approaches and their uses of technology. In the study, the main statistical model addressed was the model of regression. In several tasks students

were asked to intuitively reason about the relationship between different variables (e.g., income and health) regarding various countries or a time series of one or more countries. All students recognized a correlation between income and health, building a model of regression. For example, one student, Richard, stated: “The higher the income in a country is, the better is the health rate of children.” (Richard, worksheet 1) Students also interpreted the positive slope of the regression correctly: “That means that the countries constantly develop – in other words the GDP per person is growing – and the percentage of surviving children is heightening.” (Eva, worksheet 1) Still, students did not compare countries’ development by recognizing and building two or more models of regression in one graph (see figure 3) with one exception: “That means that poor people in India are less healthy than the rich ones whereas in Namibia the poor ones have nearly the same rate of health as the rich ones.” (Vincent, worksheet 1). Anyway, most students independently used a model of regression during their autonomous investigations: “The poorer the countries are the worse are the numbers [of other variables] or the more children they have.” (Paul, Peter and Anna, worksheet 3).

Besides using regressions, some models of probabilities were detected in the data as well. The students were asked to decide whether the person with the median income most probably comes from a low, middle or high-income country. For example, Vincent marked the height of the income of middle-income countries in the graphic of the distribution and connected the height to its probability. But some misconceptions were also observed with students building a model for this probability while

Figure 3: Examples of slides from the Gapminder learning materials

maybe having a linear (regression) model in mind, as exemplified by these remarks: “Poor income country, because 6-7 \$ is very little” (Julia, test 1) or “middle income because the number is in the middle” (Ruth, test 1).

These outcomes show that students had an intuitive access to the basic ideas of regression and correlation. The attempts to apply the model of regression to the probability theory may be rooted in the proximity of tasks. Furthermore, we suggest addressing *context*, *change* and *causality* as a part of the new framework for statistical literacy (Prodromou & Dunne, 2017) in that connection, as some students intuitively described the relationship between the variables with a focus on causality.

A second statistical idea to be mentioned here is the idea of distribution. With the learning materials on worksheet 1, students were briefly introduced to the idea of statistical distributions. All students recognized a change in the parameters of the income distribution over time and interpreted this change correctly, e.g., “Heavily concerned [with poverty] were South and East Asia (1970). Since then, Africa got poorer” (Anna, worksheet 1). Moreover, some students gave a correct interpretation of the

old-fashioned term “3<sup>rd</sup> world (in 1987)” regarding the graphic in figure 1. As they did not get any instruction on regular or irregular shapes of distributions, students were not wondering about the different shape of the income distributions of 1987 and 2015.

When asked for the central value of the income distributions in 2015 and 1987, all students gave the right number for the “regularly shaped” distribution of 2015, but around half of the students wrongly identified the higher, more distinctive peak in 1987 (see figure 1) as the centre (in terms of the median) of the distribution, although the poverty line above this peak is marked with “47%”. In our data, we have detected two answers of students autonomously differing between median and mean, but most students did not differentiate between these two. In sum, we can conclude that the ideas of distribution and the centre are intuitively accessible, but certainly should be addressed more explicitly to avoid or eliminate the misconceptions. Especially a more detailed focus on the idea of distribution regarding their shape must be explored.

The collected data show that all students adequately applied the idea of variability in different contexts. They intuitively defined and applied the idea of “variability”, e.g., in terms of “constant appearing dispensation, spread of something; [...] In Namibia there are some people, who earn very little and some who earn very much. Therefore, the spread is as large.” (Anna, worksheet 1), “the diverse levels of economy and rate of child mortality in different countries” (Sarah, worksheet 1), or “continuously occurring distribution/spread” (Clemens, worksheet 1). Moreover, all students used the idea of variability in their autonomous investigation to describe different variables. Therefore, we believe that the basic concept of variability is relatively easy to access for students who have adequate pre-conceptions of spread or range.

Relying on the reports of the teacher, the instrumentation processes (Ben-Zvi & Ben-Arush, 2014) of students can be described as unsystematic in the beginning and partly systematic while they are getting familiar with the tool. This does not seem surprising, especially since the students did not spend a long time working with the software. As students were given hints which variables to use in their autonomous investigation, the development of the instrumentation processes from unsystematic to systematic may have been supported. More detailed observation on students’ use of the Gapminder tool will be necessary to identify helpful and hindering conditions for their instrumentation processes.

## Summary

By addressing students’ pre-conceptions and intuitions on various statistical concepts with visual methods, the initial results of the study suggest that some of the basic ideas, such as models of regression, centre or variability, tend to be intuitively accessible for students, whereas especially the idea of distribution seems to demand a more extensive development. In addition, several opportunities to focus on students’ statistical literacy, related to explicating *inferences within data or context, change and causality* (Prodromou & Dunne, 2017), were detected. Offering a selection of adequate variables to explore, students’ instrumentation process using the Gapminder software was apparently supported. Results of this pilot study will lay the basis to redesign this research project and to generalize findings.

*The goal of this article is to draw attention to the need to think about learning environments and their design as a way of considering how sustainable change in the learning and teaching of statistics can be supported. The goal is not to advocate one particular approach to the design of learning environments, but rather to raise awareness of the need to consider this lens in statistics education. We first present the rationale for the importance of a focus on learning environments for statistics education. We consider six design considerations for statistics learning environments. Finally, we discuss implications and emerging directions and goals for further implementation and research.*

*Keywords: Learning environment, learning and teaching of statistics, statistics education.*

### Introduction

Many of the research studies in the learning and teaching of statistics (e.g., Ben-Zvi, Makar, & Garfield, 2018) suggest innovative approaches that differ from the traditional classroom practices through which most current statistics teachers learned this subject themselves. However, innovation which addresses only one aspect of the pedagogical context, for example introducing technological tools in teaching when assessment practices remain unchanged, is likely to have only limited impact. This article offers starting points of design for deep learning of statistics to develop students' statistical reasoning. To do this, we use a *learning environment* perspective to provide a dynamic, holistic, integrated and multi-dimensional framework for sustainable educational change in statistics. The goal of this article is to draw attention to the need to think about learning environments and their design as a way of considering how sustainable change in the learning and teaching of statistics can be supported.

A learning environment is a complex and dynamic educational system, composed of multiple factors: key statistical ideas and competencies (content), engaging tasks, real or realistic data sets, technological tools, classroom culture including modes of discourse and argumentation amongst students and between students and teachers, norms and emotional aspects of engagement and assessment methods. Integrating all these factors in order to reform the way statistics is learnt and taught is a challenging endeavor. The focus in this article is on general characteristics of statistics learning environments that need to be examined and integrated in light of the new developments in mathematics, statistics and science education, and more generally in the learning sciences. Our specific objectives are to first present the rationale for the importance of a focus on learning environments for statistics education; we provide a potential framework for considering aspects of statistics learning environments. We then develop six design considerations for statistics learning

---

<sup>1</sup> This article is based on a chapter by Ben-Zvi, Gravemeijer and Ainley (2018).

environments. Finally we discuss implications and emerging directions and goals for further implementation and research.

## Learning environments

The research literature in statistics education is filled with success stories, which are of importance to the advancement of the field, but have not had a major impact on the way statistics is taught in all levels of education. We propose that one of the reasons for this is the lack of a systematic, comprehensive and integrated approach to design for educational change (e.g., Cuban, 2003). We suggest that what is needed is change in a combination of interrelated dimensions (content, pedagogy, space, time, tasks, tools, assessment, classroom culture etc.) that can bring about significant and sustainable reform in the teaching and learning of statistics by providing a coherent framework in which each dimension operates synergistically with others. Moore (1997) similarly urged a reform of statistics instruction and curriculum based on strong synergies between content, pedagogy and technology. A learning environment perspective can provide such a framework. One of the major goals of statistics education is to educate critical, independent and statistically-literate learners who are able to study topics of their own interest and become involved in data-based decisions. A learning environment perspective can provide fertile affordances to support learners' growth and development in this direction as well as a guiding framework for teachers that can support their professional growth in statistics education.

Design dimensions of statistics learning environments that will be considered and discussed in this article are based on a number of principles arising from recent research. In particular we have drawn on research concerning the importance of prior knowledge and preference for depth over breadth (Bransford et al., 2000), the creation of failure-safe learning communities in which students can learn from their successes and mistakes (Kapur & Bielaczyc, 2012), the nurture and articulation of learners' diverse expertise, encouragement of reflection and feedback (Boud, Keogh, & Walker, 1985), formative assessment (Kingston & Nash, 2011) and enculturation into the statistics discipline (Edelson & Reiser, 2006).

The use of the metaphor of an *environment* emphasizes that classrooms are interacting social, cultural, physical, psychological and pedagogical systems rather than a collection of resources, tasks and activities or a list of separate factors that influence learning. Because of the complex nature of learning environments, successful design requires a working model of how components of the design that help frame forms of student participation and responsibility, are collectively constituted and orchestrated (Lehrer, 2009). To achieve this kind of balance and orchestration we argue that learning environments must be designed on the basis of learning theories, which can guide the design, help choose between the options and lead to better achievement of the pedagogical goals. In Ben-Zvi, Gravemeijer and Ainley (2018), we describe two theoretical frameworks that have been commonly used to guide the construction of learning environments: social constructivist theory as a background theory on teaching and learning and Realistic Mathematics Education (RME) as domain-specific instruction theory that is specific for mathematics education.

## Design dimensions for statistics learning environment

In this section, we identify design dimensions that arise from theoretical and empirical sources. These dimensions are not meant to serve as a prescription for what teachers and designers should do, but rather to provide a wide spectrum of factors or starting points, that need to be considered, aligned and balanced in designing statistics learning environments. The goal of designing effective and positive statistics learning environments occurs in a wide continuum of settings. On this continuum, this article focuses on designed learning environments rather than informal and ambient ways of learning. The goal of these learning environments is for students to develop a deep and meaningful understanding of statistics and the ability to think and reason statistically. We discuss and expand on six dimensions of pedagogical design (Figure 1) proposed by Cobb and McClain (2004), highlighting what we see as the important connections between them.

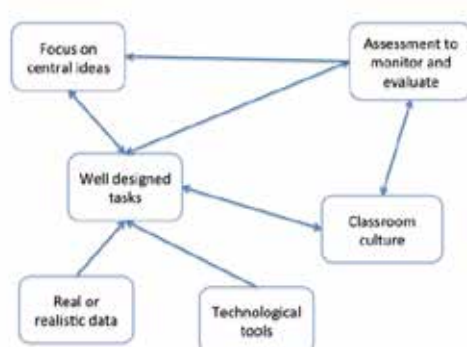

Figure 1: A web of interrelated dimensions of a learning environment

### Focus on Developing Central Statistical Ideas Rather Than on Tools and Procedures

There are several key statistical ideas that students are expected to understand at a deep conceptual level (Garfield & Ben-Zvi, 2008). These ideas serve as overarching goals that direct teaching and motivate and guide students' learning. They include data, distribution, center, variability, comparing groups, sampling, modeling, inference and covariation. Garfield and Ben-Zvi (2008), in their Statistical Reasoning Learning Environment (SRLE), advocate a focus on key statistical ideas and the interrelations among them and suggest ways to present these ideas throughout a course, revisiting them in different contexts, illustrating their multiple representations and interrelationships, and helping students recognize how they form the supporting structure of statistical knowledge.

### Use Well-Designed Tasks to Support the Development of Statistical Reasoning

An important part of a statistics learning environment is the use of carefully designed tasks, informed by research findings, that promote student learning through collaboration, interaction, discussion and addressing interesting problems (Roseth, Garfield, & Ben-Zvi, 2008). It may be argued that such tasks should be part of a well-considered instructional sequence, informed by the aim of developing central statistical ideas, which is underpinned by a *local instruction theory*. A local instruction theory typically consists of a theory about a potential learning process and theories about the means of supporting that learning process (Gravemeijer & Cobb, 2013). The former offers teachers background information, on the basis of which they may decide, on a daily basis, what learning goals to aim for.

While the latter offer them information on how potential tasks, tools, ways of interacting and the classroom culture may support the intended learning process. This information will help teachers in choosing tasks and tools, anticipating the mental activities of the students, orchestrating classroom interaction and evaluating the implied hypothetical learning trajectories.

### **Use Real or Realistic and Motivating Data Sets**

The design of pedagogic tasks in statistics must take account of the data that will be centrally involved. Data are at the heart of statistical work and data should be the focus for statistical learning as well (Franklin & Garfield, 2006). Throughout their experience of learning statistics, students need to consider methods of data collection and production and how these methods affect the quality of the data and the types of analyses that are appropriate. One approach can be to look for interesting data sets to motivate students to engage in activities, especially ones that ask them to make conjectures about a data set before analyzing it (Ben-Zvi & Aridor, 2016). Another approach would be to start with a question and then discuss what data would be needed to answer it. However the provision of real or ‘realistic’ data is not always sufficient to engage students in tasks that develop statistical reasoning unless the task poses meaningful challenges and provides opportunities to use statistical ideas in realistic ways.

Consider two kinds of activities using real data which are relatively familiar within statistics education research. The first is exploratory data analysis based on a source of real data. Although data about students like themselves may have intrinsic interest, posing meaningful questions about the data can be challenging for school students (Burgess, 2007). Open-ended exploration of relationships in the data without a clear goal may not lead them to use statistical ideas in realistic ways. The second is a sampling task, such as repeatedly drawing small samples to estimate the proportion of sweets of a particular color within a bowl. Here the statistical idea of sampling is being used in a realistic way, to answer a specific question, but the task itself is not a meaningful challenge (Ainley, Gould, & Pratt, 2015). If you really wanted to know the numbers of sweets of different colors it would be quicker and more reliable to empty the bowl and count them. What these tasks have in common is that, although based on real data, they do not emphasize opportunities for students to appreciate the utility of statistical ideas. As a result they may appear contrived and fail to engage and motivate students.

There is a further tension concerning the role and nature of data in statistics tasks. Students, particularly younger students, need to experience collecting, recording and cleaning their own data in order to develop their understandings of different forms of representation (Neumann, Hood, & Neumann, 2013). But data collection is time-consuming, often leaving relatively little time for analysis and discussion and the features of the resulting data sets cannot be predicted. Providing real world data sets, or devising data sets which are not authentic but embody the features that the teacher wants students to experience, will save time but students may find such data sets harder to understand and engage with (Arnold, 2004).

### **Integrate the Use of Technological Tools That Allow Students to Explore and Analyze Data**

The design of tasks and the ways in which students may access and explore data are significantly influenced by the range of technological tools available to support the development of students’ understanding and reasoning, such as computers, graphing calculators, statistical software and web

applets (Biehler, 2003). Students no longer have to spend time performing tedious calculations, or drawing graphs and can focus instead on the more important task of learning how to choose appropriate analytic methods and how to interpret results. Technological tools are used not only to generate statistics, graph or analyze data, but also to help students visualize concepts and develop an understanding of abstract ideas through simulations. For examples of innovative tools and ways to use them to help develop students' reasoning, see Biehler, Ben-Zvi, Bakker and Makar (2013).

### **Establish a Classroom Culture that Fosters Statistical Arguments**

The design of tasks, technological and assessment tools has to take into account the expected forms of classroom *discourse*. In statistics learning environments, the use of activities and technology allows for a form of classroom discourse in which student learn to question each other and respond to such questions, as well as explaining their answers and arguments. Cobb and McClain (2004) describe the effective classroom discourse in which statistical arguments explain why the organization of data gives rise to insights about the phenomenon under investigation and students engage in sustained exchanges that focus on significant statistical ideas.

It can be challenging to create a statistics learning environment with classroom discourse that enables students to engage in discussions in which significant statistical issues emerge and where arguments are presented and their meaning is openly negotiated. Creating a classroom climate where students feel safe expressing their views, even if they are tentative is another challenging task and is related to classroom *culture*, in which the teacher and students have to develop the corresponding classroom social norms and socio-mathematical (or socio-statistical) *norms* (Yackel & Cobb, 1996). These norms encompass the obligation for the students to explain and justify their solutions, to try to understand the explanations and reasoning of the other students, to ask for clarification when needed and eventually to challenge the ways of thinking with which they do not agree. The teacher is not expected to give explanations, but to pose tasks and ask questions that may foster students' thinking. Socio-statistical norms would be tailored to what it means to do statistics, for example what a statistical problem is, what a statistical argument is and so forth.

The shift in the classroom culture is related to a potential shift in the role of the students, from problem solvers to statisticians who analyze and represent data to make them easily accessible for decision makers. When adopting the role of a data analyst, or data detective (Pfannkuch & Rubick, 2002), students can start reflecting on the adequacy and clarity of condensed descriptions and representations of data, which may foster the reinvention of more sophisticated representations and concepts.

### **Use Assessment to Monitor the Development of Students' Statistical Learning and to Evaluate Instructional Plans**

Assessment should be aligned to well-designed tasks that focus on central statistical ideas in a discourse-rich classroom. Much of the value of changes in the other design dimensions will be lost if assessment practices are not aligned in this way, since the attention of students and teachers will be shaped by the requirements of assessment. In recent years, many alternative forms of assessment have been used in statistics classes. In addition to quizzes, homework and exams, many teachers use statistical projects as a form of assessment (MacGillivray & Pereira-Mendoza, 2011). Other forms of alternative assessment are also used to assess students' statistical literacy (e.g., critique a graph in a

newspaper) and reasoning (e.g., write a meaningful short essay), or to provide feedback to the teacher (e.g., minute papers).

Assessments need to be aligned with learning goals, focusing on understanding key ideas and not just on skills, procedures and computed answers. This can be done with formative assessments used during a course (e.g., quizzes, small projects, or observing and listening to students in class) as well as with summative evaluations (course grades). Useful and timely feedback is essential for assessments to lead to learning. Types of assessment may be more or less practical in different types of courses. However, it is possible, even in large classes, to implement good assessment practices (Garfield & Ben-Zvi, 2008, pp. 65-89).

### **Discussion: Contemporary issues and emerging directions**

The goal of this article has been to draw attention to the need to think about learning environments and their design in statistics education as a way of considering how sustainable change in the learning and teaching of statistics can be supported. We have provided six dimensions of statistics learning environments. Designing for educational change to support the development of students' statistical reasoning is a challenging task. Using a lever to make a one-dimensional change (e.g., formulate new tasks, use of a new pedagogical strategy) may make a difference that is not necessarily a sustainable change in students' understanding of statistical ideas. This article has argued for a holistic and integrated approach that advocates a learning environment where students are engaged in making and testing conjectures using data, discussing and explaining statistical reasoning, focusing on the important big ideas of statistics, using innovative tools in creative ways to assist their learning and being assessed in appropriate ways.

A key factor in this discussion is that these six dimensions, which are inter-related (see Figure 1), must be aligned and balanced. Issues of alignment are important for accelerating statistics learning both within and outside of schools. The meaning of these design principles being part of integrative whole is that using one of them separately is not enough to make deep and sustainable change in students' learning. The learning environment approach helps to interlink them. For example, the design of motivating tasks is linked to real data collection; these data can be used to build students' statistical understanding taking advantages of the innovative affordances of technological tools; productive classroom discourse is supported by the design of open-ended tasks that support argumentation and by appropriate responses by the teacher; assessment methods need to align with the design of tasks; a provision of a new tool must consider the potential interactions with content and pedagogy (Moore, 1997).

Thus we argue that pedagogical and research efforts for change must consider the interactions among these dimensions. There are however other important dimensions of learning environments that were not included in this article. One example is the emotional aspects of engagement and identity to motivate all students to participate and reflect on their experiences (Heyd-Metzuyanim, 2013). In addition, the broader community (school level policy makers, local and national authorities, etc.) plays a significant role in the constitution of the learning environment. For example, tensions may arise between required traditional examinations and alternative assessment methods employed in a

learning environment or between national curricula and an emergent and dynamic learning trajectory in the learning environment.

Further research is crucially needed to provide more well-researched holistic examples in different contexts and age levels. Systematic studies are also needed about the effectiveness of statistics learning environments, learning environment design issues, the role of alignment between the various dimensions of statistics learning environments, new possibilities for teaching and learning in innovative designs; and opportunities in cutting edge areas, such as, model-based reasoning, visual representation to teach complex abstract concepts, learning in virtual worlds, net-based collaborative teams and communities and big data.

The difficulty of demonstrating the effectiveness of learning environments, raises profound methodological issues in researching them. The learning environment approach acknowledges a complex system or ecology in which a traditional methodology is not sustainable. Instead, a design research approach (Cobb et al., 2003) is needed, where iterative design of the learning environment sensitizes the research team to the key mechanisms for learning within the design. We recommend that more attention be given to methodological aspects of researching the design of learning environments.

First steps in moving towards the learning environment perspective in the statistics education community are for researchers to consider the implications of this approach in their studies and for professional development to support teachers to consider how current curricula and materials align in the context of social, cultural, physical, psychological and pedagogical components of a learning environment. Careful and steady change over a period of time, rather than a push for radical change, may lead to a successful implementation of a learning environment in the statistics education world, both among researchers and teachers.

### Background

In the Norwegian *Curriculum for the Common Core subject of Mathematics*, there are competence aims after the second, fourth, seventh and tenth years in primary and lower secondary education. In the subject area of Statistics, there seems to be little progression through the various grades, in our opinion. The relevant competence aim after Year 4 is “collect, sort, note and illustrate data using tally marks, tables and bar graphs, with and without the use of digital tools, and converse about the process and what the illustrations tell us about the data” (Utdanningsdirektoratet, n. d.).

The competence aims after Year 10 read as follows.

carry out investigations and use databases to search for and analyse statistical data and critically assess sources; order and group data, find and discuss and elaborate on the median, mode, average and spread, and present data with and without digital tools, and discuss and elaborate on different ways of presenting data and what impressions these can give. (Utdanningsdirektoratet, n. d.)

The competence aims in Statistics after Year 10 and are in textbooks often dealt with in grade 8. In the textbook *Faktor* for grade 8 (Hjardar & Pedersen, 2014, p. 110), the following problem is marked as *difficult*. A table that shows the population for each county in Norway is given with the task: “Find the top three counties with the highest population”. In terms of difficulty, there is very little progress to see from tasks given based on the competence aims after grade 4. Even if the competence aims (“analyse statistical data”) and the related document *Mathematics: Characteristics of goal achievement* seem to support a more exploratory approach leading for instance towards informal statistical inference, our impression is that the subject area of Statistics is treated superficially and poorly in textbooks.

### Theoretical perspectives

There is already an extensive research literature on teaching experiments introducing statistical inference in middle school (see e. g. Watson, 2008). One common approach is to use graphical representations of datasets, often with the help of digital tools such as TinkerPlots (Konold & Miller, 2005), to make comparisons between samples and informal inferences about differences of populations. We intend to go one step further and introduce to middle school students test procedures that have theoretical justification in permutation methods (Ernst, 2004). The focus will be on the *significance* (perhaps without using this technical word) of difference of means, not just comparing means. Rossmann (2008, p. 17) suggests that “simulation of randomization tests

provides an informal and effective way to introduce students to the logic of statistical inference”. Zieffler, Garfield, Delmas & Reading (2008, p. 44) define informal inferential reasoning as “*the way in which students use their informal statistical knowledge to make arguments to support inferences about unknown populations based on observed samples*”.

## Developing a teaching plan

We want to develop a teaching plan aimed at grade 8 or 9 about statistical inference focusing on experiments with realistic problems, perhaps using a design-based research methodology. As mentioned we want to include permutation tests, but they will be presented to the students in an informal way. There should be no instruction about distributions or formal methods, only an appeal to the underlying logic that we hope can be intuitively acceptable for students. This last point should be one focus point of our research. We have tried out one experiment with teacher students about comparing the weight of apples and oranges in samples and then repeatedly and randomly reassign which fruits are “apples” and which are “oranges”. How does the real difference in weight compare with the randomized differences? If there is no significant difference in weight between apples and oranges, then the real difference should not be among the most extreme in the simulation. This is an example of the logic behind permutation tests. But is it *informal* inferential reasoning? This is a question we should have in mind when developing the plan.

The details of the teaching plan are still very much in development. One idea we have is to offer the permutation tests to the students late in a sequence of lectures, where earlier in the sequence more student-driven activities, perhaps involving digital tools and graphical representation of data sets, are planned and where students are encouraged to use their own reasoning. We have done the activity with apples and oranges three times with teacher students and gotten valuable feedback. We want to develop this into a larger project involving real classroom settings.

<sup>2</sup>Christelijk Lyceum Delft, The Netherlands

*The scarce research on teachers indicate that they often misinterpret histograms. We conjecture that the confusion of histograms with case-value plots is the source of many misinterpretations. Therefore, the question for this study is: what are the most common strategies of secondary school teachers when interpreting histograms and case-value plots? To answer this question, we use a method that allows for a more in-depth analysis of twelve teachers' interpretations of graphical representations than was ever possible before: eye-tracking combined with retrospective verbal reports. Preliminary results show that several teachers apply a case-value plot interpretation strategy on a histogram. Furthermore, some participants use an area interpretation strategy or histogram interpretation strategy applied to a case-value plot. In addition, gaze data suggest that teachers use strategies that did not reach awareness and therefore will not be reported during thinking aloud protocols.*

*Keywords: Secondary school mathematics, statistics, verbal report, graphical representations, bar graphs.*

## Background

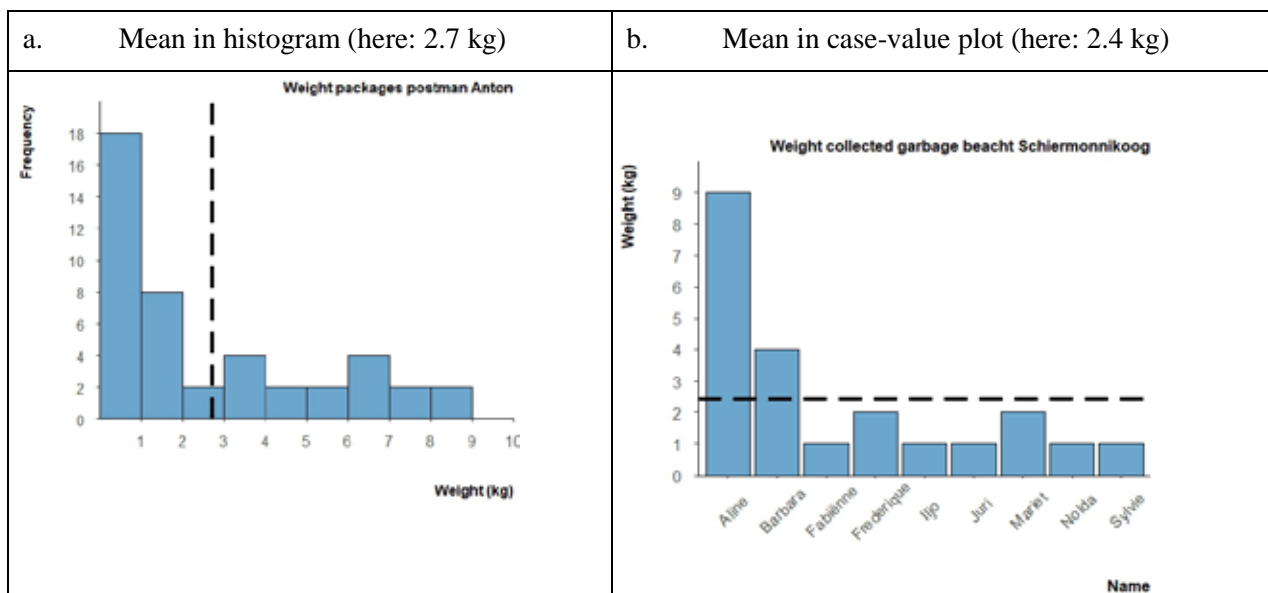

Histograms are very difficult to interpret (e.g., delMas & Liu, 2005; Lem, Onghena, Verschaffel, & Van Dooren, 2013). Misinterpretations of histograms persist despite many interventions aiming to tackle these misinterpretations. For example, Kaplan, Gabrosek, Curtiss and Malone stated in 2014: “the fact remains that the data indicate not only that students entering a statistics course have certain misconceptions about histograms, but also that these misconceptions persist after instruction” (p. 17). In an extensive review of more than 80 publications (Boels, Bakker, Van Dooren & Drijvers, 2019) we identified that most misinterpretations regarding histograms relate to the misunderstanding of two statistical big ideas: *data* and *distribution*. One of the important insights that goes with understanding the big idea of *data* is knowing how many variables are at stake. A misinterpretation existing amongst students, teachers and even researchers is that histograms could display two variables instead of what is correct: only one statistical variable<sup>1</sup> (the one given on the horizontal axis, see Figure 1a; e.g., Boels, Bakker, et al., 2018). The big idea of *distribution* encompasses centre, shape and variability. One misinterpretation is that a histogram has more variability when it is “bumpier,” meaning more variation in the frequency (the heights of the bars) instead of the variation in the data (e.g., Boels, Bakker, et al., 2018; Dabos, 2014; delMas & Liu, 2005; Lem, et al., 2013).

---

<sup>1</sup> In line with other researchers (e.g., Garfield & Ben-Zvi, 2007), we prefer the term variable over attribute because some people may use attributes for categorical data only.

In line with other researchers (e.g., Cooper & Shore, 2010; Garfield & Ben-Zvi, 2007; Kaplan et al., 2014) we conjecture that the confusion of histograms with case-value plots is the source of many misinterpretations. A histogram and a case-value plot share several salient features (e.g., vertical bars, numbers along the vertical axis). The differences between those two graphical representations—regarding the number of depicted statistical variables as well as the measurement level of the data—are less apparent for most people.

As the number of variables differ in a case-value plot compared to a histogram, so does the interpretation of measures of centre and variability. In Figure 1 the difference for a measure of centre—the mean—is shown for a case-value plot and a histogram. This depicted difference in assessing the mean, also influences the assessment of both the variability and the shape of the distribution. In a histogram, teachers have to look at the horizontal positions of the bars in combination with the bars' heights to assess centre and variability. In contrast, in a case-value plot, teachers have to look at the variation in the heights of the bars only.

**Figure 1: The mean weight (dashed line) is assessed differently in a histogram (left; Item 2) than in a case-value plot (right; Item 8)**

The confusion of histograms and case-value plots can explain many of the misinterpretations with histograms reported in the literature but does not answer the question what exactly goes wrong when people interpret histograms. To tackle the persisting problem of misinterpreting histograms, we need to deepen our understanding of the kind of strategies that people use when interpreting histograms. In an exploratory case study we found that students are often unaware that histograms and case-value plots ask for different interpretation strategies (Boels, Ebbes, Bakker, Van Dooren, & Drijvers, 2018). From our personal experience, we conjectured that the same holds true for some of their teachers. The aim of our current study is therefore to identify the most common strategies of teachers when interpreting histograms and case-value plots. Hence, the question for this research is: what are the most common strategies for secondary school STEM teachers when interpreting histograms and case-value plots?

To answer this research question, we used eye-tracking combined with a retrospective interview. The eye-tracking makes it possible to literally see teachers' strategies when solving a task. The advantage of eye-tracking over other techniques, is that it makes an in-depth study possible of the strategies with more detail than was ever possible before. In our exploratory case study, for example, we found that several participants had an initial preferred strategy that they were not aware of and were therefore not reporting during the retrospective interview (Boels, Ebbes, et al., 2018). Eye-tracking has several advantages over other research techniques. For example, using assessments items only, such as CAOS (e.g., delMas, 2005) has already been done extensively and cannot easily answer the question about strategies. Using a thinking aloud protocol (TA) to discover strategies works well if people verbalize their strategy during TA—although TA might slow down the task solving process. But when people need to explain their strategy—why they do what they do, this alters their cognitive processes (Ericsson, 2006) and is therefore unsuitable for our goal. The study of Van Gog and Jarodzka (2013) showed that a retrospective interview improves when a cue is added: the replay of participants' eye movements during the recall. Considering all these arguments we decided to use eye-tracking combined with retrospective reports to unravel teachers' strategies.

From a previous exploratory study with six university students (Boels, Ebbes, et al., 2018) we obtained the following two interpretation strategies that are relevant for the current study: a histogram interpretation strategy and a case-value plot interpretation strategy. A histogram interpretation strategy is associated with a vertical looking pattern and reading of the numbers on the horizontal axis for locating the mean. Furthermore participants using this strategy may use statements as for example “balancing” the graph. A case-value plot interpretation strategy is associated with a horizontal looking pattern and reading of the numbers on the vertical axis. On top of that, these participants may use words like “redistributing” or “make all bars even” (e.g., same height). The exploratory study leads us to the following conjectures for the study reported here:

- 1) The most common strategy for interpreting histograms is a case-value plot interpretation strategy, followed by the histogram interpretation strategy.
- 2) The most common strategy for case-value plots is a case-value plot interpretation strategy. Only a few teachers will apply a histogram interpretation strategy onto a case-value plot.
- 3) Several teachers will have an initial preferred strategy independent of the type of graph at stake.

## Method

In total twelve items were either constructed (two) or re-used (ten) from the exploratory study (Boels, Ebbes, et al., 2018). The teachers were asked to either estimate the arithmetic mean of the data in the graph or to compare the arithmetic means of two graphs as estimating the mean can be seen as a necessary prerequisite for assessing the variability. A second reason for choosing the mean was that the target audience of the larger project are secondary school students who are more familiar with measures of centre than measures of variation and the same holds true for their teachers. From the exploratory study we learned that the multiple-choice answers might work as an anchor for the participants (e.g., Tversky & Kahneman, 1974) in items with only one graph. Hence, for the six items with a single graph we used open questions.

We constructed (or re-used from the previous study) a case-value plot for every histogram, with the same salient features such as number of bars, “shape,” range and variable (weight), resulting in a total of twelve questions. Figure 1 gives an example of Item 2 and 8. Items were constructed that differed systematically on the relevant features but that were the same for irrelevant though sometimes salient features as recommended by Orquin and Holmqvist (2017). These features were carefully chosen so that a teacher applying the same interpretation strategy on both the histogram and the case-value plot could be expected to answer the question for the case-value plot correctly and for the histogram incorrectly, and vice versa.

Similar to the previous study we arranged the items in such a way that there were never more than two of the same graph types (histogram or case-value plot) in succession. As we expect that most teachers who confuse case-value plots with histograms will apply a case-value plot strategy onto a histogram, we started with two single left-skewed histograms. This was done to avoid priming (e.g., Lashley, 1951). The first two single histograms were followed by an item in which participants had to compare two case-value plots. Graphs with the same salient features (e.g., Item 2 and Item 8) never directly followed one another. The question for the histogram in Figure 1a was: What is approximately the average weight of the parcels delivered by Anton? The question for the single case-value plot in Figure 1b was: What is approximately the average weight that has been collected per person? In Figure 2, an example of an item with two histograms is given (Item 5). The multiple choice answer options for comparing two histograms were for example: a) Willem delivers on average the heaviest parcels, b) Julia delivers on average the heaviest parcels, c) the average weight of the parcels is approximately the same for both.

**Figure 2: Example of Item 5 in which teachers were asked to compare two histograms and indicate whether the mean weight was higher for one of the two postman or roughly the same**

The sample included twelve secondary school teachers of three Dutch secondary schools preparing for college or University grade 7 to 12 (ten teachers were from the same school). Participation was voluntary and science and mathematics teachers were asked to participate. Consent was signed before starting the task. To minimize distractions, the teachers were tested in a one-on-one setting. An explanation was given on the aim of the study as well as how to operate the equipment and software. After completing the task—that included the twelve items mentioned in this research as well as some other items that are not discussed here—participants were asked to report what they thought as well

as their strategy during the specific tasks. To improve the quality of these retrospective verbal reports we used their own gazes as a cue (Van Gog & Jarodzka, 2013).

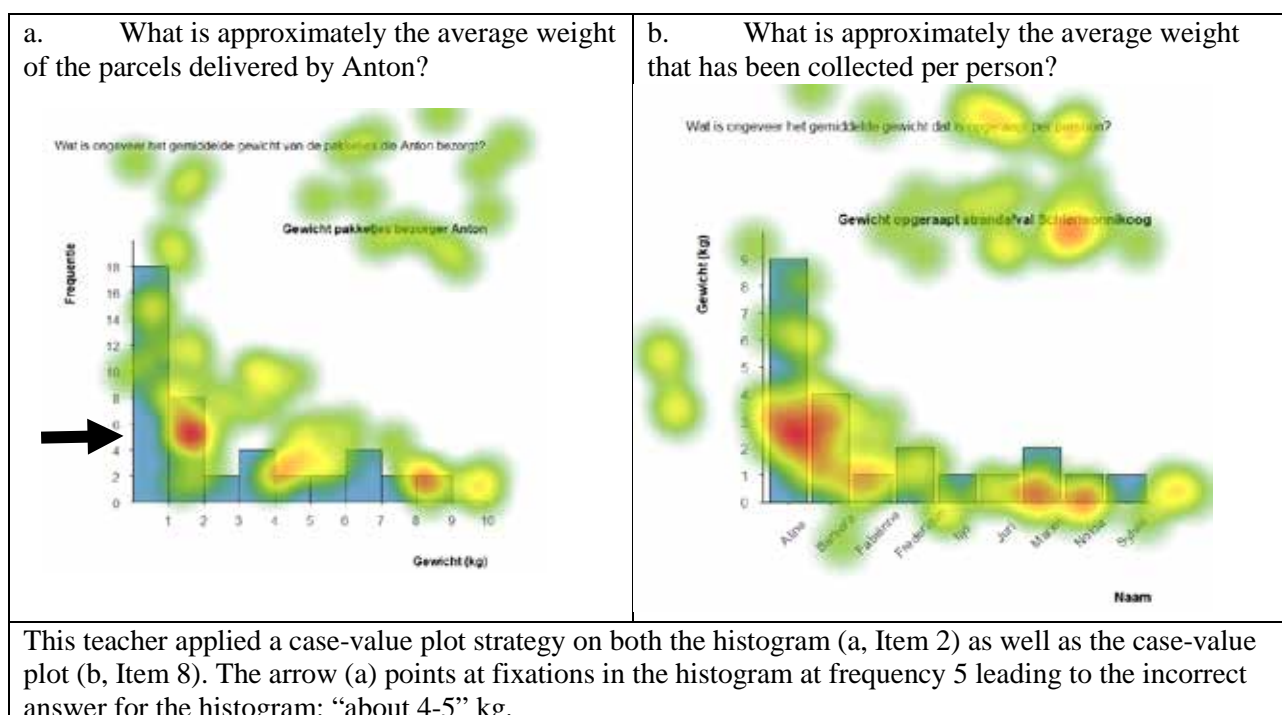

An eye-tracker measures where a person looks on a computer screen and uses infrared light to detect the position of the eyes. The Tobii Pro X2-60 eye-tracker was used, mounted on a laptop with a 13-inch screen by using magnetic mounting brackets. The sampling rate was 60 Hz. The fixations (where people look) and saccades (going from one fixation on the screen to another) were recorded real time by the software Tobii Pro Studio 3.4.5. The first author qualitatively coded the gaze data and verbal reports using open, axial and selective coding (Corbin & Strauss, 1990). Furthermore, the coding was checked with gaze data. The gaze data were displayed in heat maps that show where participants looked. The colouring is from green (few fixations) via yellow to red (many fixations), see Figure 3. In Table 1 an example is given of the analysis of gaze and verbal data of one participant. In the next part of the study, not reported here, an analytical analysis of the pattern will be done by using so called areas of interest (AOIs) such as the graph area, vertical axis, horizontal axis and so on and also—if technically possible—by using specialised artificial intelligence software.

Item number	Gaze data – open codes	Verbal data – open codes	Selective code for strategy
2 (single histogram)	Reads question Reads title graph Looks at top highest bar Looks in middle of graph area (white space) Looks at low bar (7-th) Looks in middle of graph area (white space) Looks at low bar (9-th) ...	Look at title Looked at highest and/or lowest number on y-axis Look how often lowest bars occur Low bars do not contribute much to mean Higher bars contribute more to mean ...	Case-value plot interpretation

**Table 1: Example of qualitative analysis (open coding) of gaze and verbal data of a participant as well as the selective code of the combined data**

## Results

The most common strategies of these teachers were: a histogram interpretation strategy, a case-value plot interpretation strategy and an area interpretation strategy. Several participants seemed to use the same interpretation strategy for both the histograms and case-value plots. An example of a case-value plot interpretation strategy applied to a histogram is shown in Figure 3a. The heat map shows many fixations around frequency 5. The teacher said during the eye-tracking: “Well, uh, about 4 or 5 or something like that.” In the retrospective report this teacher said: “I looked at the highest number on the y-axis [...]. I looked at the lowest frequency. If this occurs less than you have to count that less and [...] the highest beams you take more of these, so to speak, from their weight. [...] and I have taken the frequency as kilos.” This teacher realised at the end of the tasks that s/he systematically used the frequency axis as the weight axis and refers to that in the explanation. The correct answer for this item would be any number between 2 and 3.4 with the actual mean for this specific dataset being 2.7.

**Figure 3: Histogram (a) and case-value plot (b) from Figure 1 with heat map overlay**

An example of an area interpretation strategy is where a teacher looked at a histogram using a vertical looking pattern and in the verbal data mentioned that the area of the bars left and right of the mean have to be of the same size. An example of a histogram interpretation strategy applied on a case-value plot is when a teacher looked at Item 10—the case-value plot variant of Item 5 in Figure 2—and said:

Teacher: Only the spread with uh that that right one [the case-value plot on the right with two bars less but the same number of names] is less than that [pause] left one.

Researcher: And why is the spread less?

Teacher: Well, because there are two numbers added thus are, it goes further on.

Researcher: Yes, so you are pointing now [on the screen]: they are wider.

Teacher: Yes, he is wider.

This teacher concluded that the mean was the same and that only the spread differed. In a case-value plot, a higher difference in heights of the bars indicates more spread. The case-value plot with the two students who collected nothing had the lowest mean and most spread. Another finding is that many teachers do not read axis labels and/or graph titles. But even if they do, this does not guarantee that they interpret the histogram or case-value plot correctly. The gaze data indicate that the teacher mentioned above did read the graph title and the labels on the vertical axis—weight (kg)—but still applied the wrong strategy.

## Conclusion and discussion

The first conclusion is that the most common strategy for interpreting means in histograms is a case-value plot interpretation strategy. Using a case-value plot interpretation strategy for a histogram implies not understanding that a histogram is for one statistical variable only and that histograms

therefore differ from a case-value plot with two depicted statistical variables. As stated in the background section, understanding the big idea of data implies understanding how many variables are depicted in a histogram. This conclusion is therefore in line with the finding in our review study on histograms (Boels, Bakker et al., 2019). Furthermore it is in line with misinterpretations found by others (e.g., Cooper, 2008; Lem et al. 2013). In addition, we speculate that—although several teachers did not read labels on the axes—teaching teachers to read labels will not suffice to eliminate the confusion of histograms with case-value plots, as—for example—the teacher mentioned earlier who applied a histogram interpretations strategy onto a case-value plot, did read the labels.

The second conclusion is that teachers sometimes used an area interpretation strategy for finding the mean in a histogram. In this interpretation strategy the data in the histogram are correctly interpreted (e.g., the statistical variable is on the horizontal axis) but the misinterpretation is related to the big idea of *centre*. Instead of the mean, the median is found with this strategy of equal areas. This finding is in line with findings from others (e.g., Cooper, 2008). We speculate that this interpretation strategy is due to excessive exposure to symmetric—specifically normal—distributions in histograms in schoolbooks and statistics courses where mean and median are indeed the same.

In addition, the gaze data can be used to identify strategies that participants may not be aware of and therefore will not be reported during thinking aloud protocols or retrospective interviews. Eye-tracking therefore adds a new research tool to researchers' toolkit, making it possible to analyse participants' strategies in more detail than was ever possible before. Furthermore, researchers and teacher educators can use these results to better design curriculum materials. Finally, in line with the wish list from CERME10 in 2017 (Bakker, Hahn, Kazak, & Pratt, 2018), this research concentrate on teachers as well as contributes to teachers' Statistical Knowledge for Teaching (Groth, 2007).

This research is funded with a Doctoral Grant for Teachers from The Netherlands Organisation for Scientific Research, number 023.007.023 awarded to Lonneke Boels.

*Every day we deal with all sort of information presented in different ways. Thus, we need to be able to interpret and analyze that information. This research tends to understand the statistical knowledge of future teachers of the first years and to enlighten the importance of high-level tasks in the access of that knowledge. We assumed an interpretative paradigm and developed an action-research project. The participants were students of the 2<sup>nd</sup> year of Basic Education course (N=95) who were attending the curricular unit named Data Analysis and the four teacher/researchers who taught the classes. Data was collected through a statistical knowledge assessment instrument (at the beginning of the curricular unit), participant observation, and students' protocols. The results illustrate the importance of high-level tasks in the access of statistical errors in order to (re)construct statistical knowledge with meaning for the future teachers.*

*Keywords: statistical learning, pre-service teacher education, high-level tasks.*

## Introduction

Being a citizen became a complex and multifaceted task. Mathematical literacy, particularly statistical literacy, is essential to act as a critical and participative citizen. According to Wallman (1993), statistical literacy is “the ability to understand and critically evaluate statistical results that permeate our daily lives – coupled with the ability to appreciate the contributions that statistical thinking can make in public and private, professional and personal decisions” (p. 1). Thus, this argument highlights that statistical literacy deals with data in context, which is also stated by Watson (2006). Therefore, it is important that students must have a good preparation in learning of statistics being able to put in practice the (statistical) knowledge appropriated (Caseiro, Ponte, & Monteiro, 2015).

This research arises from the need to identify and to know the statistical knowledge that the students that enter the Degree in Basic Education of the Lisbon Higher School of Education reveal. This is of particular importance insofar as statistics enable the development of essential abilities and competencies in an increasingly technological society and, given the specificity of this higher education course, to train future teachers of the first years, which constitutes a unique opportunity for change. In this way, the problem that originated this investigation is related to the little statistical knowledge that the students of the course of the Degree in Basic Education reveal at the beginning of their higher education. The research questions that emerge from this problem and which we addressed in this article are: (1) What statistical knowledge do the students of the Basic Education Degree course reveal at the beginning in the curricular unit Data Analysis?; and (2) In what way do the mathematical tasks proposed, helps us to detect students' difficulties?

## Mathematical tasks

According to NCTM (2007), students should be active constructors of mathematical knowledge and teachers should be facilitators of students' learning by providing learning experiences in which students can engage in mathematical tasks given meaning to the (mathematical) knowledge and developed abilities and competencies (e.g. mathematical reasoning, mathematical communication, critical sense, among others). But for that, the nature of mathematical tasks should be different from the usual one (exercises), as well as the working instructions and the way these same tasks are explored in the class (Stein, Grover & Henningsen, 1996). Boston and Wolf (2006) state that the nature of the tasks influence students' learning and the way they engage with mathematical work itself. In other words, "different types of tasks provide different opportunities for students' learning and place different expectations on students' thinking" (Boston & Wolf, 2006, p. 7).

Stein and his colleagues (1996) categorised the nature of the tasks according the level of cognitive demand: between low and high-level. A task with low-level of cognitive demand is associated with the memorization and/or application of procedures without attribution of meaning. Thus, it approaches what Skemp (1978) called instrumental knowledge since that the students are only able to apply rules, formulas or algorithms and they are not able to mobilize this knowledge when they are in other contexts or situations. A task with high-level of cognitive demand is characterised by creating opportunities for students to make connections between (mathematical) concepts and its different representations, to allow different approaches for the same task according to the previous (mathematical) knowledge appropriated by each students, and creating opportunities for mathematical communication (Boston & Wolf, 2006; Stein et al., 1996). Thus, according to Skemp (1978) it corresponds to the relational knowledge. In this way, it is up to the teacher to select, adapt and/or elaborate tasks with different natures regarding students' characteristics, interests and needs (Machado & César, 2013).

The error and the way in which it is faced by the students and teachers assume an important element in the learning process. As stated by Abrantes, Serrazina and Oliveira (1999), when we think in terms of learning, making errors or saying things imperfectly or incompletely is not to be avoid, it is something inherent in the learning process. Therefore, it is important to provide opportunities in which students engage in mathematical tasks that cast doubt on what they took for granted.

### **Dimensions of statistical work**

Franklin and her colleagues (2007) stated that a statistical investigation is characterised by four steps: (1) posing a question; (2) collecting data; (3) analysing data; and (4) interpreting the results. Kader and Perry (1994) suggest an additional step which is related with the dissemination of the results.

According to Shaugnessy (2007) all the steps of investigative cycle are essential in statistical work and recall the four stages of solving mathematical problems presented by Pólya (1945/1973): to understand, to plan, to execute and to review. This author also states that teachers give little time to the problem and to the plan steps. Most students are only taught "pre-statistical" topics, in which the hard decision concerning the problem formulation, conception and production of data are already done for them. This situation makes the investigative cycle poorer (Shaugnessy, 2007).

### **The knowledge in Statistics of the future teachers**

Statistical investigations give students the opportunity to reflect on the information that surrounds them, to develop statistical literacy and to appropriate of statistical knowledge and the knowledge about the stages of the process (Martins & Ponte, 2010).

Some studies point out the difficulty of future teachers in carrying out statistical investigations. Stohl (2005) even mentions that the future teachers of the first years make elementary errors in statistical concepts, similar to those of the students themselves at these levels of education. At the level of statistical work, Heaton and Mickelson (2002) reveal the difficulty of the future teachers in accomplishing the data collection process, not recognizing the need to create a standard unit of measure to standardize the data.

In the representation of data and interpretation of graphs, Espinel, Bruno and Plasencia (2008) conclude that the future teachers involved in their study demonstrate difficulties in the interpretation of graphs and in the selection of graphs suitable for the representation of the information. At a more specific level, they demonstrate difficulty in differentiating quantitative and qualitative variables, which translates into the difficulty of distinguishing between a bar chart and a histogram.

In the dimension of the central tendency measures, Burrill (2008) states that the future teachers demonstrate difficulties in adapting the graphical representations to the different existing measures, opting for an incorrect representation, almost always through bar graphs.

## Method

This study is part of the project “Statistical knowledge of students of primary and secondary levels of education and of students of the Basic Education course of the Lisbon Higher School of Education”, whose main goals are: (1) to access the statistical knowledge of students throughout their education and those that integrate, for the first time, the Basic Education graduation; and (2) to analyse the path carried out by the future teachers, in terms of the development of statistical knowledge, during the accomplishment of the mentioned degree.

When entering the Basic Education Degree, at the Lisbon Higher School of Education, the Data Analysis is the first and only curricular unit that students have in the field of Statistics and it appears in the 1<sup>st</sup> semester of the 2<sup>nd</sup> year of the cycle of studies. Thus, when students attend this curricular unit they reveal difficulties in working with certain statistical knowledge, especially at the beginning of the course. In this way, the problem that originated this investigation is related to the little statistical knowledge that the students of the course of the Degree in Basic Education reveal in the beginning of their higher education. The research questions that emerge from this problem and which we address in this paper are: (1) What statistical knowledge do the students of the Basic Education Degree course reveal at the beginning in the course unit Data Analysis?; and (2) In what way do the mathematical tasks proposed, helps us to detect students’ difficulties?

We assumed an interpretative approach (Denzin, 2002) and developed an action-research project (Mason, 2002). The participants in this study were all students in the 2<sup>nd</sup> year of the Basic Education course (N=95, 2017/2018 academic year), who were attending the curricular unit named Data Analysis. The ages range from 18 to 37 years old. We also considered as participants the four teacher/researchers who taught the classes.

Data was collected through a statistical knowledge assessment instrument (at the beginning of the curricular unit), participant observation, and students' protocols. Such data was then treated and analysed through a narrative content analysis (Clandinin & Connelly, 1998), performed in a successive and in-depth way.

## Results

### The task

The task presented to the students (Figure 1) was intended, along with other instruments applied, to make a diagnosis of the statistical knowledge with which students of the Basic Education course starts their higher education. In order to allow students to reveal the maximum of their knowledge, the variables chosen for the proposal were thought of in order to contemplate the different types of statistical variables. In this way, this task is considered high-level of cognitive demand (Boston & Wolf, 2006; Stein et al., 1996), since the students are required to make connections to underlying mathematical ideas, with the possibility of using several strategies and representations. If this task was limited to engaging students in using a defined procedure (e.g. a direct question: what is the mean of the following data?), the students would not be so confident and could give up on the task. This situation would not facilitate the teachers' access to students' statistical knowledge.

1. Collect the following data from five colleagues who have not been in your work group:			
Gender	Age (in years)	Date of Birth	Height
Eye color	Shoes number	Hand palm (in cm)	Name of a public figure (artist/politician/writer/...)
Number of glasses of water you drink per day	Birth place (village/town and country)	If you recicle (paper/glass/plastic)	Means of transport you use to go to school
Estimate time you spend on coming to school	TV Program/series you usually watch	Average daily time spent watching TV	Name of one of your favorite TV news presenters
If you have driver license	Average daily time spent reading newspapers / magazines	Average time to get ready when you wake up	On a scale of 1 to 5 (1 bad environment) give your opinion about the environment among students
2. Now that you have your data, arrange and organize it so, in order to convey to the class a close idea of the obtained results.			

**Figure 1: Mathematical task statement**

### Students' performances

Throughout our observation of the work of the groups it was possible to verify the inexistence of any kind of planning or organization from them. As soon as they received the task, practically all members of the groups got up and started collecting data with their colleagues, showing that they did not bestow importance to this phase of statistical research, as pointed out by Shaughnessy (2007). However, this situation is usual to happen if the students did not have this experience, during their academic path. As might be expected, this aspect was perceived by some students when organizing the data and later by others, during their discussion in a large group. An example of the lack of planning of the groups concerns how they have collected data on the size of their colleagues' hand palms. It was apparent that different elements of the same group were collecting this data in a different way: while some measured the hands of their colleagues when they sit with the hand as stretched as possible, others did not take that aspect into consideration and others measured the base of the hand instead of the

palm, as requested. Another aspect in which the lack of planning was evident relates to the fact that some members of the same group have collected data with the same colleagues.

On the other hand, the way students decided to represent the data collected also revealed some difficulties in the construction of statistical representations, as well as the non-attribution of meaning to the value of statistical measures determined by them.

Regarding continuous quantitative variables, a common error concerns the use of a bar chart to represent the data instead of the use of a histogram. As can be seen from the example in Figure 2, some students decided to construct a bar chart to represent the heights of the colleagues. In addition to this situation, the representation of the intervals in which the students decided to present the data demonstrates a difficulty on the part of the students, since, as it is visible in the given example, they put the same value of the data in two different intervals, not being able to perceive in which it was actually counted.

**Figure 2: Performance of a Group A1**

Nevertheless, the opposite also happens, that is, the students construct histograms with data of nominal qualitative variables (Figure 3), as that is the case of the place of birth.

**Figure 3: Performance of a Group C1**

This error (construction of histograms and bar graphs as if the same representation were and independently of the type of variable) was demonstrated by several students, which seems to be related to the fact that the students assume that any graphical representation with bars is a bar chart.

Another detected situation concerns the construction of pictograms with discrete quantitative variables data. As can be seen in the example on Figure 4, students showed some difficulty in realizing which values should appear on the pictogram axis and which values should be represented with the

symbol chosen for the pictogram. Thus, in the example presented, the group decided to put in the axis the frequencies with which the data appeared and to represent, with the chosen symbol, the number of glasses of water drunk daily, mentioned by the colleagues. In short, students had shown some difficulties in the choice of the adequate graph representation, which is in line with Batanero, Godino, Vallecillos, Green, and Holmes (1994).

Figure 4: Performance of Group A2

On the other hand, through the example shown in Figure 5 it is possible to verify the non-attribution of meaning to the value of statistical measures by these students. In the presented example, the group decided, after constructing a pie chart, to determine the Mode, Mean, and Standard Deviation of the Eye Color variable data. As a nominal qualitative variable, it would be expected that students, even if they performed the calculations to determine the latter two statistical measures, find that the values obtained would not make any sense for the variable under study. In this way, students revealed knowledge in calculating the Mean and Standard Deviation of statistical variables, but were not able to give meaning to the values obtained, which means that they can only mobilize instrumental and non-relational knowledge (Skemp, 1978), as would be desired.

Figure 5: Performance of Group B2

## Final Remarks

The analysis shows that students who entered in higher education, in this specific case, in a course for teachers of the first years, reveal lack of knowledge and difficulties in terms of procedures, representations and attribution of meanings to statistical measures.

Regarding statistical procedures, the students' lack of knowledge was evidenced when they did not give importance of carrying out a work plan before collecting data. This aspect seems to be in agreement with what is mentioned by Shaughnessy (2007). On the other hand, the students' difficulty in selecting the most adequate statistical representation to use in relation to a particular type of variable may also be associated with this aspect. But, at the same time, most tasks ask students to

construct a specific representation, which does not allow them to think about which is the most appropriate and advantageous to use in each situation. Also in relation to the difficulties presented in the construction of pictograms with data of discrete quantitative variables, it is possible to notice that, since most of the tasks students are used to do already show parts of the constructed representations, such as the axes in a graph, it limits the experience of the construction of a graph from scratch. Finally, the fact that students calculate statistical measures without analyzing their relevance to the type of variable under study seems to be associated with a mechanized teaching of formulas, which students know without hesitation, but which they can't attribute any meaning.

In this way, this work shows the importance of performing high-level tasks not only for the development of students' statistical knowledge but also for the detection of their errors and difficulties so that we, as teachers, can adjust our classes and, more specifically, the tasks to be proposed, not to what we suppose students need to develop and learn, but to what we concretely know they need.

This paper is part of the Project *O conhecimento estatístico dos/as estudantes do ensino básico, secundário e da Licenciatura em Educação Básica da Escola Superior de Educação de Lisboa* funded by CIED (ESELX/IPL-CIED/2018/A27).

*This paper presents the following set of eight design principles for informal statistics inference (ISI) education for upper primary education in settings where limited time is available for ISI: Create awareness of inferential claims before engaging students in ISI via statistical investigations; use a context for which the students have no clear expectations of the outcome or which challenges current beliefs; use a question that highlights the need for an inferential claim; use a large population that makes sampling inevitable; use activities with tangible populations and samples in which generating representative samples and recording data is easy and quick; use data that require little descriptive analyses; and use the principles of growing samples and repeated sampling in order to create sampling variability. Three exemplar ISI activities illustrate how the design principles can be used to design new ISI activities and evaluate existing ISI activities.*

*Keywords: Primary education, informal inferential reasoning, informal statistical inference, statistics education.*

## Introduction

An introduction to informal statistical inference (ISI) in primary education has been advocated by various researchers (Makar, 2016; Makar, Bakker, & Ben-Zvi, 2011). The literature provides examples of activities that introduce ISI in upper primary education (De Vetten, Schoonenboom, Keijzer, & Van Oers, 2018a; Kazak, Pratt, & Gökce, 2018; Leavy, 2009). While design principles for statistics education in general are available (Ben-Zvi, Gravemeijer, & Ainley, 2018), the literature does not report on a comprehensive list of design principles for ISI education for upper primary education. The aim of this paper is to bring together a set of design principles that have been reported in the literature alongside design principles that are distilled from recent research with primary pre-service teachers (De Vetten et al., 2018a; De Vetten, Schoonenboom, Keijzer, & Van Oers, 2019) with a view to generate design principles that apply to upper primary education. The design principles presented in this paper can be used for the design of ISI activities that require relatively little time (e.g. up to an hour), but still allow for an introduction of all key concepts of ISI.

## Theoretical background

ISI can be seen as part of the broader field of statistics. For statistics education in general, it is suggested to focus on developing central statistical ideas, to use real, or realistic, and motivating data, and to integrate the use of technological tools that allow students to explore and analyze data (Ben-Zvi et al., 2018). Most of these principles are useful also for ISI education in primary

education. The design principles we describe below therefore build on these principles. However, for eliciting IIR, these principles are not sufficiently specific.

A number of design principles have been targeted specifically towards ISI. First, activities where students are asked to make predictions about another or a larger sample based on the sample at hand, such as the growing samples heuristic (Bakker, 2004), appear to be an effective principle for activities that aim to engage students in IIR (Ben-Zvi et al., 2018; Makar, 2016). Some recent research involving pre-service teachers (De Vetten et al., 2019) and upper primary school students (Kazak et al., 2018) utilizing the growing sample design principle indicates mixed results. The participants used the data as evidence in making predictions of the shape of the distributions of larger samples and thus looked beyond the data. However, pre-service teachers also tended to neglect uncertainty and make deterministic predictions. Moreover, most predictions made of other samples mimic the shape of the original sample, thus suggesting that students did not have a picture in their mind of a sample distribution being the result of an overarching population distribution. Rather, they may have thought that the original sample “produces” the predicted sample. De Vetten et al. (2019) suggest that this could be due to the absence of repeated sampling elements in the activities used. Including such elements confronts students with different sample results, which may make them aware that an inference based on one sample includes some uncertainty.

A second design principle for ISI activities is to have students compare two sample distributions and draw a conclusion about the difference between the means in the population (Zieffler, Garfield, delMas, & Reading, 2008). However, research evidence shows mixed results in terms of the success of eliciting IIR, due to a number of (contextual) factors. First, without proper teacher intervention, such tasks appear not to sufficiently stimulate students to engage in IIR (De Vetten et al., 2019; De Vetten, Schoonenboom, Keijzer, & Van Oers, in press; Pfannkuch, 2006), and, in our research, pre-service teachers tend to restrict their attention to descriptive analyses. Another factor that may contribute to the absence of IIR in activities where students compare two distributions (De Vetten et al., 2019, in press; Pfannkuch, 2006) was that these activities did not involve repeated sampling, thereby missing the opportunity to view sampling variability. Third, while the sample distributions are visible, the populations remain abstract. Finally, tasks that compare sample distributions require substantial time for the necessary descriptive analyses, which goes at the expense of the available time and energy for inferential reasoning (De Vetten et al., 2018a).

A third design principle is to use a modelling approach in which a population is modelled (often using software, such as Tinkerplots). Samples are drawn from this hypothetical population distribution in order to develop an appreciation for the likelihood of various sample outcomes and an understanding of sampling variability (Manor & Ben-Zvi, in press). This approach requires more time and puts demands on the computer skills of the teacher and the student, and may therefore be less suitable for general upper primary students in settings with limited time and support.

In sum, findings from recent studies points towards a number of conclusions regarding effective design principles for ISI education and requirements for effective design principles: First, the use of growing samples and repeated sampling is recommended in order to create sampling variability and to show that usually larger samples reduce sampling variability and thus reduce the uncertainty of

the inference. Second, it appears to be important to make students aware of the distinction between sample and population and when an activity requires a generalization beyond the data. Third, an overemphasis on descriptive analyses, arising from activities involving the comparison of sample distributions, may reduce the opportunity to engage in IIR. Fourth, in many primary school settings with limited available time and support the extensive use of technological tools may not be feasible.

## Design principles

Using the above conclusions about (requirements for) effective design principles for statistics education in general and ISI education in particular we formulated eight principles for the design of ISI activities for primary education.

In particular, seven of these design principles are specifications of how statistical investigations activities should look like when the goal is to introduce students to ISI. The first design principle stands apart as it is undertaken prior to students being actively involved in conducting statistical investigations.

1. Create awareness of inferential claims and of the distinction between sample and population, before engaging students in ISI via statistical investigations

De Vetten et al. (2019) and De Vetten et al. (in press) showed that most pre-service teachers appear to only describe the data, rather than engage in IIR. In De Vetten et al. (2018a) we first engaged pre-service teachers in an activity that was designed to make them aware of the existence and use of inferential claims. This activity appeared to promote an awareness of inference. Throughout the intervention the participants retained this awareness.

2. Use a context for which the students have no clear expectations of the outcome, or for which the outcome challenges students' current beliefs.

When the outcome is unpredictable or challenges students' current beliefs, students are stimulated to engage in inferential investigations and to search for explanations (Makar et al., 2011). When the outcome is predictable students may not engage in critical IIR (see for an example De Vetten et al., 2018a).

3. Use a question that clearly highlights that an inferential claim is required and use a population with a sufficiently large number of elements that surveying the entire population is impossible within a limited time frame.

The question posed should lead the student to conclude that merely analyzing the sample data descriptively is insufficient. However, even when considerable care is taken to formulate a good inferential question (e.g. using the guidelines from Pfannkuch, Regan, Wild, & Horton, 2010), other factors may cause students to restrict their attention to descriptive analyses (De Vetten et al., 2019). Therefore, combining a tangible population (see principle 6) with a population that consists of too many elements to survey in its entirety makes drawing a sample natural and generalization inevitable (De Vetten et al., 2018a).

4. Use activities that support the generation of a representative sample and that stimulate critical reflection on the representativeness of the sample.

The effect of this principle is that students may be willing to accept the sample data as reliable evidence for making inferential claims. In case an ISI activity does not permit students to draw representative samples, but only non-representative ones (such as convenience samples from their own class), students may be reluctant to engage in IIR because generalization based on such non-representative samples is not possible anyway. Ideally, the activity is such that it is possible to draw both representative and non-representative samples, with the effect that discussions are elicited about ways to draw a representative sample.

5. Use activities in which generating samples and recording data is easy and quick and in which students preferably collect data themselves.

The effect of this design principle is that an excessive focus on data collection is avoided. At the same time, the data generation and recording process should allow students to make sense of the data and should facilitate mathematization (Treffers, 1987) and engagement in IIR. Therefore, it is preferable that students collect their own data.

6. Use activities with a tangible population and sample.

The effect of this design principle is that students remain aware of the distinction between sample and population and that they are required to make a claim that pertains to the entire population.

7. Use data that require little descriptive analyses.

In the PPDAC-cycle, data analyses comes before interpretation of the results, including making inferences (Wild & Pfannkuch, 1999). Spending too much time on descriptive analyses of the sample data leaves little time and energy for inferential reasoning (De Vetten et al., 2019; Leavy, 2009). The effect of this design principle may be that sufficient time, energy and attention is left for IIR, while at the same time engagement in descriptive analyses helps students to make sense of the results and facilitates further mathematization (De Vetten et al., 2018a).

8. Use the principles of growing samples and repeated sampling in order to create sampling variability.

The effect of using the principle of repeated sampling is that students will consider the uncertainty of their inferences, because sample results will vary (Saldanha & Thompson, 2002). The effect of using the principle of growing samples is that students will see that larger samples usually reduce sampling variability and thus reduce the uncertainty of the inference (Bakker, 2004).

### **Applying the ISI design principles – Three example activities**

This section describes three ISI activities and how the design principles can be used to design new ISI activities and evaluate existing ISI activities. The first activity was designed with the design principles in mind, while the second and third were not. We evaluate the extent to which they are in line with the design principles.

#### **Activity 1: What is the most frequently used word?**

The first activity (De Vetten et al., 2018a; De Vetten, Schoonenboom, Keijzer, & Van Oers, 2018b) was implemented in two settings: in a class of second-year pre-service primary school teachers and

in three primary classrooms (grade 3, 5 and 6). The activity centers round a pile of children's novels, that constitutes a population, and the question "Which word is most frequently used in this pile of novels?" First, students make a list of the top 5 words they think are most frequently used in the pile of books. Next, students discuss how to find out which is the most frequently used word. Taking a sample is the expected response. The sampling procedure is discussed. Small groups of students draw small samples and then pool their results in multiple large samples. The inferences for small and large samples are compared. In this way, it could be shown that the proportion that yields the same most frequently used word is greater for large samples than for small samples. If the proportion of samples with the same most frequently used word is high, students could be willing to accept the possibility of making uncertain inferences based on one sample.

**Figure 1: Pooled sample results in the activity "What is the most frequently used word?"**

This activity was designed with the design principles in mind and it aligns well with all but one of the design principles. The activity is clearly inferential and uses a tangible and large population and visible sample (design principles [DP] 3 and 6). It requires that students consider how to take a representative sample and it allows for generating a representative sample (DP 4). Students take a book from the pile and count the occurrence of the top 5 words on a number of lines or a page, making sampling, recording and analyzing simple (DP 5 and 7). Without the need to rely on technological tools growing samples and repeated sampling can be achieved by having individual students draw samples and by combining students' samples (DP 8). The number of students may, however, limit the possibilities for repeated sampling for larger samples. Our research shows that pre-service and primary school students were engaged in inferential reasoning (De Vetten et al., 2018a, 2018b). However, the activity included repeated sampling only for smaller samples. It thus missed the opportunity for students to see the sample results converge for larger samples. Repeated sampling for various sample sizes appears crucial to teach students to balance between sampling representativeness and sampling variability. Finally, the activity might not completely align with DP 2, because students may have beliefs about the outcome, based on information they have about word frequency in books in general (De Vetten et al., 2018a).

### **Activity 2: How many yellow balls are in the Black Box?**

The activity "How many yellow balls are in the Black box?" (Van Dijke, Drijvers, & Bakker, 2018) was implemented in a grade 9 pre-university secondary classroom. The activity has students

investigate and estimate the number of yellow balls in a black box, filled with a mix of 1,000 yellow and orange balls, by looking through a small viewing window. It is expected that students will shake the bottle in order to take samples repeatedly and that they will use the average of their sample as an estimate. Findings are recorded and discussed by students as part of a whole class discussion. Following this, a larger viewing window is opened on the black bottle, the experiment repeated, and findings recorded. The contention is that experiences with the physical black box experiment support the development of an informal understanding of samples and sampling variability and promote investigation of the effect of repeated samples and larger sample size.

While this activity was not designed based on the list of design principles presented in this paper and its effects on students' reasoning has not yet been reported, it appears to align well with the principles. As the number of yellow balls is determined by the educational designer, students cannot have any expectations of the outcome (DP2). Generalization is natural, as it is obvious that the sample results are only a means to make a claim about the population (DP 3). It has a visible and large population and a visible sample (DP 3 and 6). It is easy to obtain a representative sample as yellow and orange balls are mixed and shaking the bottle results in a random sample. Since obtaining a non-representative sample appears to be hard in this activity, it might not stimulate critical reflection on sample representativeness. However, sampling variation may lead to discussing representativeness (DP 4). The context, question, sampling, recording and analyzing are simple (DP 5 and 7). Repeated sampling is achieved by repeatedly shaking the bottle and counting the yellow balls and by combining small group results in a whole class graph, while growing samples is possible by enlarging the viewing window from 40 to 80 balls (DP 8).

**Figure 2: Black box, used in the activity “How many yellow balls are in the Black Box?”**

### **Activity 3: Comparing math attitude of men and women**

This activity is a standard activity in which students are asked to compare two samples and draw a conclusion whether in the population the groups differ (see for example De Vetten et al., 2019; De Vetten et al., in press). One example of such an activity is shown below, where the activity also involves a growing samples activity. It was implemented and evaluated in three groups of first-year pre-service primary school teachers (De Vetten et al., 2019). The driving question was whether in the population there is a difference in math attitude between men and women. During three rounds the students answer this question and make predictions of the shape of the distributions of larger samples.

This activity was not well-aligned with a number of design principles, in particular with the visibility of the population (DP 6), the simplicity of the analyses (DP 7), and the possibilities for repeated sampling (DP 8). Indeed, we showed among the pre-service teachers engaged in this activity, there was a strong tendency to restrict attention to descriptive analyses, rather than to engage in inferential reasoning (De Vetten et al., 2019). The teacher also had strong ideas of the difference between the groups in the population and, therefore, some had problems treating the data as evidence (DP 2). We also contend that, when the population elements are humans, it may be complex to obtain a representative sample, thus leading students to put less trust in the sample and reducing their willingness to make generalizations (DP 4 and 5). On the positive side, the complexity of the sampling process stimulates critical reflection on sample representativeness (DP 5) and the immensity of the population encourages students to take a sample (DP 3). Although the design principles offer suggestions to improve this activity, in particular using repeated sampling, some elements, such as a visible population from which it is easy to generate a representative sample, might not easily be rectified.

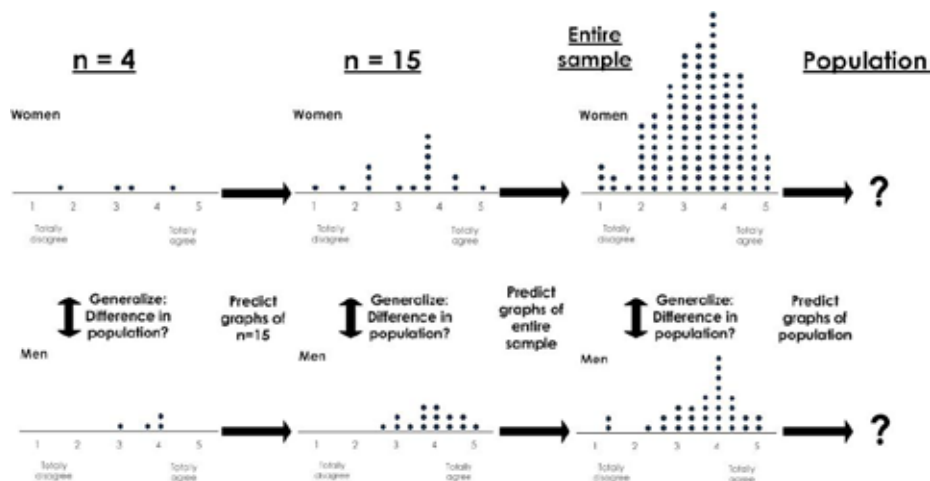

Figure 3: Overview of the activity “Comparing math attitude of men and women”

## Conclusion

Designing ISI activities for primary education that align with all the design principles is not straightforward, as it demands very good knowledge of ISI and educational design. We have suggested two activities that to a large extent align with the design principles. Teachers can effectively use these activities in their classrooms. The design principles can also be used by educational designers to align their own activities with the design principles and elicit IIR more effectively. For example, the activity in which two samples are compared could incorporate repeated sampling, and the averages and measure(s) of dispersion could be provided, so that more time can be spent on IIR. Some of the design principles for ISI education presented in this paper are well-known and have been reported before, but some are based on recent ISI education research. In this way, we aim to provide a comprehensive set of design principles, based on recent evidence, that can be useful for educational designers and are ready to be corroborated by future research. Moreover, the principles are potentially applicable beyond the primary education (teacher) setting, to other settings where the design for activities is necessary when first introducing students to ISI.

# Chilean primary school difficulties in building bar graphs

Danilo Díaz-Levicoy and Pedro Arteaga

University of Granada, Spain; parteaga@ugr.es

*Keywords:* Bar graphs, building, difficulties, primary education.

## Introduction and method

A relevant part of the information we face every day is given in statistical graphs, whose interpretation is often needed to make different decisions; therefore there is a need for citizens to achieve enough graphical competence. These reasons led countries like Chile to introduce statistical graphs in the primary education (MINEDUC, 2012).

In a previous study (Díaz-Levicoy, Batanero, Arteaga & Gea, 2016) bar graph were the most common representations in the Chilean curricular guidelines and textbooks. Consequently in this research we intended to assess the students' difficulties in building these graphs.

This research was aimed to identify the 6th and 7th grades Chilean school children's difficulties in the construction of bar graphs, which are recommended in the curricular guidelines and is the most frequently presented graphic in the Chilean textbooks.

To achieve this aim we analyzed the responses of 745 students, from 13 different educational centers and with an average age of 12.3 years to the task reproduced in Figure 1 in which students should form the frequency distribution of data.

**Task.** The following data result of a survey where children were asked for the number of brothers and sisters: **0, 1, 3, 2, 2, 3, 2, 4, 1, 2, 1, 2, 0, 2, 3, 1, 1, 0, 2, 4, 0, 1, 2, 3, 1, 1, 2, 2, 2**  
Buid a bar graph that summarise this information

**Figure 1: Task given to the students**

## Main results

We classified the students responses in correct, partly correct or incorrect according to the following criteria, following an inductive and cyclical process characteristic of content analysis and considering the results of previous studies:

- Correct responses correspond to bar graph that represent the data and use the criteria for these representations.
- In partly correct graphs there are minor errors, such as forgetting the general title, or using

bars with different distance between them.

- In incorrect graphs the representation of data make no sense.

Type of graph	6th (n=380)	7th (n=365)
Correct	4,7	7,9
Partly correct	40,3	44,1
Incorrect	31,3	17,8
Do not complete	23,7	30,1

**Table 1: Percentage of students according their responses**

Results are presented in Table 1, where there are no significant differences between both grades. Results are better than those reported by Bivar (2012) and worse than those by Fernandes, Moraes & Lacaz (2011) and Evangelista, Oliveira & Ribeiro (2014) although in these last studies students did not need to form the distribution. The most frequent errors in our research were representing the list of data without forming the distribution (15.4% of students), non-proportional scales (13.7%), lack of titles or labels (34.6%) and bars with different width or separation (18.1%). Some students committed several of these errors. All these results suggest the need of reinforcing the teaching of graphs in Chilean basic education.

Results show the high difficulty, since only 50% of students produce correct or partially correct graphs. The differences between the two groups were not statistically significant. More details about the errors made by the students can be read in Díaz-Levicoy (2018).

Project EDU2016-74848-P and group FQM126 (Junta de Andalucía).

# How Realistic Mathematics Education approach influences 6<sup>th</sup> grade students' statistical thinking

Bedriye Doluzengin<sup>1</sup> and Sibel Kazak<sup>2</sup>

<sup>1</sup>Pamukkale University, Denizli, Turkey; [bedriyedoluzengin@gmail.com](mailto:bedriyedoluzengin@gmail.com)

<sup>2</sup>Pamukkale University, Denizli, Turkey; [skazak@pau.edu.tr](mailto:skazak@pau.edu.tr)

*Using Mooney's (2002) framework describing four levels of middle school students' statistical thinking across four different statistical thinking processes, this study aims to investigate the effectiveness of the use of Realistic Mathematics Education (RME) approach on 6<sup>th</sup> grade students' statistical thinking levels. A quasi-experimental with pretest-posttest comparison group research design was used. In the experimental group the unit on 'data handling and analyses' was taught using RME approach while in the control group it was taught traditionally using the textbook. The data analysis showed that although there was no statistically significant difference between the two groups with regard to their statistical thinking scores, the overall growth at Level 4 across statistical thinking processes was higher for the students who were taught using the RME approach than for those taught traditionally.*

*Keywords: Realistic mathematics education, statistical thinking, middle school students.*

## Introduction

We are surrounded by a huge amount of information in our daily lives and it is becoming more important to make sense of the information. To do so, individuals need higher order thinking skills such as questioning, making interpretation and estimation, drawing inference, critical thinking and reasoning. Curricular reforms emphasize these skills in students' learning. For example, the Turkish National Mathematics Curriculum (MEB, 2018) aims to develop students' understanding of mathematical concepts and their use in the daily life, reasoning skills in problems and ability to detect inadequate reasoning, metacognition, making mental calculations and estimations. Similarly, earlier in the Netherlands such reform aimed to change the education system which was based on memorizing (Van den Heuvel-Panhuizen, 1996). In 1971, Freudenthal and his colleagues laid the foundations of Realistic Mathematics Education (RME) with the aim of teaching the connection between real life and mathematics (Van den Heuvel-Panhuizen, 1996). For Freudenthal (1991), two key points in RME are: (1) mathematics should be close to students' everyday lives and (2) mathematics is a human activity.

In daily life, we encounter with various data on newspaper, television and social media. Statistical concepts enable us to make decisions and solve real-world problems using data. However, students' difficulties in learning of statistics and probability can hinder these. Some of the sources of these difficulties in Turkish middle school students appear to be the teaching of statistical concepts and procedures without connections, memorization rather than conceptual understanding, and learning without concrete examples (Çakmak & Durmuş, 2015). This implies that statistics must be relevant to students' experiences and real life situations. The use of RME approach in teaching can support making the statistical problem situation become real for students since the context plays an important role in statistics.

While there are studies on the effective use of RME in learning of other mathematical topics, such as percentages (Van den Heuvel-Panhuizen, 2003) and integers (Ünal Aydın & İpek, 2009), there is a scarce of research in teaching statistics using RME. Therefore, this study, which is part of the first author's master's thesis work, sought to examine the effectiveness of RME approach on 6<sup>th</sup> grade students' statistical thinking. The research questions addressed in this paper are: 1) Is there a significant difference in students' statistical thinking posttest scores using the RME approach compared to traditional method? 2) What are the students' thinking levels with respect to the statistical thinking processes before and after the intervention in each group?

## **Statistical thinking**

Statistical thinking refers to comprehending the meaning of statistical concepts and understanding where, why and how they are used (Garfield & Ben-Zvi, 2008). That is, statistical thinking is not just calculating something or defining it. It is also about reasoning, making interpretations, predictions and inferences about data. Statistical thinking is important in solving a statistical problem about a real-world phenomenon through an inquiry cycle, called PPDAC (Problem-Plan-Data-Analysis-Conclusion) (Wild & Pfannkuch, 1999). The PPDAC cycle starts with understanding and defining a problem. Then what to measure and how to collect data are planned. Data collection phase is followed by analyzing data through looking for patterns and constructing tables and graphs. Finally, data are interpreted and conclusions are made and communicated.

To interpret middle school students' statistical thinking Mooney (2002) considers four statistical processes used in Jones et al.'s (2000) framework for elementary students: describing data (explicit reading of data presented in visual displays), organizing and reducing data (arranging, categorizing, and summarizing data using measures of center and spread), representing data (constructing visual display of data) and analyzing and interpreting data (identifying patterns in data and making inferences and predictions from the data). According to Mooney's refined framework, students' progress through four levels of thinking in each of these processes: Level 1-idiosyncratic, Level 2-transitional, Level 3-quantitative and Level 4-analytical. In Level 1, student shows no awareness of the given data; gives answers according to his/her own experiences or feelings; cannot use concepts correctly; and cannot read the given situations. In Level 2, student shows little awareness of the problem but it is still not sufficient; the solutions may contain partially correct answers. In Level 3, student shows full awareness of the problem; can correctly use concepts and formulas, and express what they mean and why they are used; can correctly see and explain the relationships between concepts; however his/her solutions or demonstrations may contain some errors. Besides, s/he can use different representations of a given data set and make transitions between them with small errors. In Level 4-analytical, students can do all procedures without any error. That is, s/he can read the given data fully, make connections, use these relationships and necessary computations correctly as well as explain how and why s/he uses them. In addition to these abilities, s/he can display the given dataset with various representations and make transitions between them without any error.

Using Mooney's framework, Koparan and Güven (2013) examined statistical thinking levels

of 90 Turkish middle school students. They found that 6<sup>th</sup> grade students' statistical thinking generally was at Level 1. For example, the proportions of students at Level 1 varied across four statistical thinking processes: 49,3% in describing data, 65,3% in organizing and reducing data, 74,2% in representing data, and 80,8% in analyzing and interpreting data. These results showed that almost half of the students had difficulties in reading of data contained in tables and graphs. Moreover, majority of them failed to both construct a complete and appropriate display of data and compare datasets and make inferences based on data.

### **Realistic mathematics education (RME)**

Freudenthal's (1991) view of mathematics as a human activity indicates that knowledge becomes the individual's own knowledge only if s/he interacts with and discovers it. To do this, the individual should actively participate in learning situations and deeply understand the meanings of mathematical concepts and their usage. According to Freudenthal, learning mathematics takes place via mathematization, which refers to the process of experiencing the discovery of the mathematics concept. In RME, mathematization is essential; without it, the process of learning mathematics cannot be completed (Freudenthal, 1991). Freudenthal (1991) expresses two forms of mathematizing as follows: Horizontal mathematization is transition from real world to mathematics and the vertical mathematization is doing mathematics in its world. In this study we focus on horizontal mathematization which takes place when the student encounters a mathematical problem and s/he starts to solve it. In this process, student makes drawings, identifies patterns and so on to transfer the real world problem to mathematics.

According to Freudenthal (1991) to learn mathematics, the student actively participate in the process, experience the discovery of mathematical concepts, try to solve the problem, develop ways and then the knowledge becomes his/her own. The teacher guides students when they need. One of the most important parts of RME is the problem situation, which should be concept oriented and make students curious enough to solve the problem.

### **Method**

To explore the effectiveness of RME approach on students' statistical thinking, a quasi-experimental with pretest-posttest comparison group research design was used since random assignment was not possible. The study was conducted in two intact 6<sup>th</sup> grade classes where the first author taught mathematics at a public school in Aydın, Turkey in the spring of 2018. In the experimental group (n=25), the unit on 'Data Handling and Analysis' was taught using RME approach while in the control group (n=24) it was taught traditionally using the textbook determined by the Ministry of Education. Both classes were taught over a three-week period.

### **Data Collection and Analysis**

The instrument used in this study was the statistical thinking test with seven open-ended questions, some of which were adapted from Koparan and Güven (2013) while others were written by the authors. The questions were addressing the four statistical thinking processes: describing data (question 5), organizing and reducing data (questions 2 and 3), representing

data (questions 1 and 4), and analyzing and interpreting data (question 6 and 7). After experts' evaluation of the test items, it was piloted with 75 sixth graders (in other classrooms in the same school and the same school year as the research) to determine its reliability. The Cronbach's alpha coefficient of the test was found 0.76, which is considered acceptable (Baykul & Güzeller, 2014). Then, the test was administered in both groups to assess students' statistical thinking levels before and after the intervention.

Students' responses on pre- and posttests were coded by both authors and scored using the rubric developed based on Mooney's (2002) framework for statistical thinking levels. There was 88% consistency between two coders. Disagreements were discussed and consensus was reached. The independent samples t-test showed that there was no difference on statistical thinking pretest scores between the groups initially. In the posttest analysis, Mann Whitney U test was used to determine the difference between the groups since the control group data were not normally distributed. Also, descriptive statistics were used for the seven-item test to examine the change in students' thinking levels before and after the intervention.

### **Procedure and Tasks**

In the control group, the 'Data Handling and Analysis' unit was taught with a traditional approach using the 6<sup>th</sup> grade mathematics textbook (Güven, 2014). The teacher followed the structure and order in the textbook and the problems given in the textbook were solved by the students. In the experimental group using the RME approach, both low and high ability students worked in small groups since both weaker and stronger students can benefit when working in heterogeneous groups (Freudenthal, 1991). Moreover, students first worked in groups and then the whole-class discussion of students' work took place. Ground rules for working together in groups were established with the students and implemented throughout the lessons. These were the rules to promote effective group work, such as "while someone is speaking, others must listen" and "in a group every member must work and help each other".

The Frog Olympics task was adapted from Kazak, Pratt and Gökce (2018) and implemented using the RME approach in the experimental group over eight class periods (each class period=40 minutes). The aim of the task was to create a problem situation that can be viewed real by the students as they engage in all four statistical thinking processes. In the activity students tried to determine which frog would be the best to go to the Olympics. First, students made two different origami frogs that could jump. Each group had one big frog and one small frog. The arithmetic means of these frogs' jumping distances were very close but the range values were not. Then the problem situation was introduced and the students were asked to determine the best jumping frog for the Olympics jumping race. Each group determined a start line and made each frog jumped 13 times on their desk. For each trial they measured the distance jumped and recorded the jumping distance in cm by rounding their measurement into the nearest integer. Next, groups were asked to make a frequency table and each group presented their data to the whole class. Then they were asked to make a graphical representation of the data, i.e. bar graph, using their frequency tables. By doing this, they were expected to make connections between different representations of a dataset. The following teaching episodes focused on analyzing data and making decision. Using their prior knowledge from the science classes, they calculated the range and mean of their datasets and

discussed together in their groups to decide which frog was better in jumping. Students already knew how to compute mean and range, but using them to compare two datasets was a new task for them. During the whole-class discussion, some groups thought that the small frog was better while some thought the big frog was better, and the teacher let them argue about their decisions. While groups were presenting their analysis and decisions, they had to explain why it was like that. Therefore, groups began to compare and contrast their ideas and a decision was made by a whole-class at the end of the discussion. In the next task, over the course of four class periods, the students were asked to collect data about their jump distances and record them during their physical education class. In the schoolyard, each group member jumped 13 times like frogs and another student measured the distance jumped. Then they made frequency tables and bar graphs of their data. As seen in the RME tasks students are expected to experience the whole statistical thinking process in PPDAC (Wild & Pfannkuch, 1999) while the textbook used in the control group puts more emphasis on calculations.

## Findings

Before the intervention, independent samples t-test results showed no significant difference in the statistical thinking test scores for both groups ( $t(47) = 0.18$  and  $p=0.986$ ). In the posttest analysis, Mann Whitney U test indicated that although the mean rank of the experimental group (26.44) was higher than that of the control group (23.50), there was no statistically significant difference between the groups ( $p=0.47$ ). Since the experimental group had the highest rank, descriptive statistical analysis was used to look closely for the changes in students' thinking levels with respect to the statistical thinking processes for each group.

Figure 1 shows the distribution of the experimental group students' statistical thinking levels for each question organized by the four statistical thinking processes on the pretest. Each column represents the item on the test and the statistical thinking process measured by that item. Colored sections of each column show the statistical levels of students and the number of students in each level for each question. For example, in Figure 1 the first column at the bottom shows the item on describing data (question 5) and there are 18 students at Level 1, 4 students at Level 2, 1 student at Level 3 and 2 students at Level 4.

According to Figure 1, before the intervention students in the experimental group mostly exhibited Level 1 thinking with regard to describing data (question 5), representing data (question 1 only) and analyzing and interpreting data (question 6 and 7). For organizing and reducing data (questions 2 and 3), they generally demonstrated Level 3 thinking. Only a few students exhibited Level 4 thinking overall. Similar to Koparan and Güven's (2013) findings, students' levels of thinking initially were generally at Level 1.

**Figure 1: Experimental group students' statistical thinking levels with respect to statistical thinking processes (by questions) on the pretest**

Figure 2 shows the experimental group students' statistical thinking levels on the posttest. Overall, most development was seen in students' thinking levels with regard to representing data and organizing and reducing data as almost half of them were at Level 4. In addition, about half of the students demonstrated Level 3 or Level 4 thinking for analyzing and interpreting data. However, slightly more than half of the students still exhibited Level 1 thinking with regard to describing data.

**Figure 2: Experimental group students' statistical thinking levels with respect to statistical thinking processes (by questions) on the posttest**

Figure 3 displays the control group students' statistical thinking levels for the statistical thinking processes on the pretest. While slightly less than half of the students exhibited Level 1 thinking with regard to describing data, majority of them demonstrated Level 1 thinking for representing data and analyzing and interpreting data. There were very few students demonstrating Level 4 thinking for each process.

**Figure 3: Control group students' statistical thinking levels with respect to statistical thinking processes (by questions) on the pretest**

Figure 4 shows the control group students' statistical thinking levels for the statistical thinking processes on the posttest. Students mostly exhibited Level 1 thinking for describing data and Level 3 thinking for organizing and reducing data, and analyzing and interpreting data. On the other hand, students' levels of thinking tended to be at Level 1 and Level 2 with regard to representing data. Overall, there was a growth in the development of students' thinking after instruction, but less compared to the experimental group.

**Figure 4: Control group students' statistical thinking levels with respect to statistical processes (by questions) on the posttest**

## Conclusions

In this study, there was no statistically significant difference in the students' statistical thinking posttest scores between the experimental group and control group. However, our descriptive statistical analysis of the change in students' thinking levels with respect to the statistical thinking processes revealed further insights about the development of students' thinking during the RME activity and the traditional instruction.

After the instruction, the least development in students' thinking levels was seen for describing data process both in the experimental group and the control group. With regard to organizing and reducing data process, there was usually development from Level 1 to Level 3 or Level 4 in the experimental group while many students' thinking levels shifted from Level 1 to Level 3 in the control group. The most development was seen in representing data process with the positive shifts in almost all students' thinking in the experimental group and with many of these was at Level 4. There were also a few shifts in student's thinking for representing data from Level 2 and Level 3 to Level 4 in the control group. While the control group students' thinking levels were mostly at Level 3 and Level 4 for analyzing and interpreting data process after the instruction, the experimental group students' thinking levels tended to shift slightly to Level 3 and Level 4. This could be due to the emphasis given to calculating statistical measures in the textbook used in the control group.

Overall, our findings suggested that the instruction using the RME approach helped students to develop their statistical thinking mainly for representing data and organizing and reducing data processes. For these two processes there was a noticeable increase in the number of students demonstrating Level 4 thinking while there was a corresponding decrease in the number of students exhibiting Level 1 thinking after the instruction. For analyzing and interpreting data process, the increase in the number of students was mainly at Level 3 thinking with a corresponding decrease at Level 1 thinking after the instruction. However, the findings indicated that students would need more experience in describing data when engaging in the RME activity as well as using the textbook. These results are consistent with previous research (e.g. Mooney, 2002) showing low student scores in describing data but high scores in analyzing and interpreting data, organizing and reducing data or representing data processes.

The non-significant statistical test results can be due to the sample size, which is comprised of about 25 students in each group. A study with larger sample size would give more reliable results. The present study is limited to quantitative methodology of data collection. In future a qualitative method can be undertaken for a deeper study of the change in students' statistical thinking after an intervention using the RME approach.

# Repurpose and extend: making a model statistical

Michal Dvir and Dani Ben-Zvi

University of Haifa, Faculty of Education, Haifa, Israel; [dvirmich@gmail.com](mailto:dvirmich@gmail.com)

*The goal of this article is to examine how learners' repurposing of a model they had previously constructed, possibly by extending its features, can support young learner's reasoning with key statistical features. This process is facilitated by a learning trajectory integrating multiple real world and probabilistic modeling tasks. We introduce our framework describing young learner's reasoning with informal statistical models and modeling (RISM) and focus on a key element in the framework: young learners' expectations regarding the data that can be collected (or generated) from a conjectured population. We offer an illustrative case study of two-sixth graders' reasoning, focusing on a specific model they had constructed and repurposed throughout their investigation, how its features developed and how it ultimately matured to include an underlying probabilistic mechanism. We discuss how this relates to our notion of expected data and close with suggested implications.*

*Keywords: Statistical model, statistical modeling, integrated modeling approach.*

## Introduction

There has been a growing interest in the statistics education community in statistical modeling as a pedagogical paradigm to developing learners' statistical reasoning. However, a deeper understanding of what statistical modeling entails is needed to better exhaust its pedagogical potential, especially with regard to young learners. In particular, a better understanding of how novices can be encouraged to construct models that are accompanied with uniquely statistical features, such as accounting for possible variability – that of the data explored, as well as of the sampling procedure that yielded it – is still warranted. The purpose of this article is to explore this, based on an illustrative case study of a pair of sixth grade students' (12 year olds) participation in a uniquely designed learning environment. We track a specific model they had constructed, and gradually repurposed as they participated in various modeling tasks. The new roles assigned to the model were also accompanied by extending and refining some of the models' features, gradually becoming more 'statistical' – that is, it eventually featured uniquely statistical features that distinguish it from a non-statistical model.

## Background – The RISM framework and the IMA

A model – a representation serving an explanatory or descriptive purpose (Hesse, 1962) – would serve as a statistical model if it was constructed for a statistical purpose, typically meaning: 1) the phenomenon it is intended to explain has a variability aspect, and 2) utilizing it includes employing probabilistic considerations (Brown & Kass, 2009). The latter is associated with the notion that the description a statistical model offers should be non-deterministic in its nature (Budgett & Pfannkuch, 2015). However, when young learners are the modelers, an informal alternative is necessary, void of the conventional procedures and calculations. Within the context of a statistical inference, a statistical model (formal or informal) needs to serve a dual representative purpose: simultaneously depicting both a conjecture about the explored phenomenon (Konold & Kazak,

2008) and its underlying probabilistic mechanism (Pfannkuch & Ziedins, 2014), as well as the data itself. It is this dual representative purpose that has inspired our framework for depicting young learners' *reasoning with informal statistical models and modeling* (RISM).

The RISM framework suggests describing the statistical modeling process as a continuous development of a set of key elements portrayed in Figure 1. The dual representative purpose of the model is translated into two planes: the data and the conjecture plane. In both, the novice modeler gradually constructs a simplified version of either the explored phenomenon (the phenomenon plane, bottom of Figure 1) or his abstract conjecture (the conjecture plane, top part). The latter may be trivial for an experienced statistician, already familiar with a vast variety of readymade statistical models and formal fit assessment procedures, but challenging for a novice. Alternatively, co-constructing two concurrent models – a data model depicting observed patterns in the data, as well as a conjecture model depicting the data expected to be collected – and assessing their compatibility, can serve as an informal alternative to the practice of model fit evaluation (Dvir & Ben-Zvi, 2018).

**Figure 1: The RISM framework's snapshot**

Worth noting is the role the expected data serve in this depiction of the informal statistical modeling process: as the expert statistician's readymade abstract conjecture is a statistical model, it should be already accompanied with previously known considerations regarding the data it can generate, and how the resulting generated data may vary dependent on the type of the model and sample size. In cases where the model is lesser known, the expert would seek to investigate how the data generated from it would behave. However, a young modeler would not typically be aware of the formally expected behavior of such generated data, nor that this behavior may vary and should be explored. Thus by 'expected data' the framework merely refers to the learners' (typically naïve) perception of the data one might collect from the investigated population if his conjecture were true. We believe this expectation is critical when considering whether the investigated conjecture model can be considered a statistical model. For it to be one – the expectation should express some (albeit informal) understanding of the probabilistic considerations associated with generating data from a model.

For this reason, integrating an investigation of the conjecture model's probabilistic mechanism may be beneficial in supporting young learners' reasoning with statistical models and modeling. Therefore, *the integrated modeling approach* (IMA, Manor & Ben-Zvi, 2017) suggests following a 'real world' inquiry with a 'probability world' inquiry, in which the probabilistic considerations of interest becomes the main subject of investigation. The probabilistic inquiry is typically initiated by

students' creating a dynamic model using the TinkerPlots Sampler<sup>1</sup> (Konold & Miller, 2015), based on their real world conjecture models. They then draw multiple simulated (same sized) samples from it, compare between them and eventually construct a sampling distribution of a chosen statistic. The data examined in the probability world is therefore no longer a single sample, rather multiple samples, and the conjecture and inferences made describe the samples' behavior. These inferences, although different in their nature, are closely connected to the real world inquiry that instigated the probabilistic exploration and therefore can be then related back to inform a progression in the real world inquiry.

The real world conjecture model is therefore utilized in the probability world to serve a different purpose (probabilistic rather than real), however what is examined is its underlying probabilistic mechanism, mirrored by the sampling variability students observe. This can lead to refinements of the Sampler model from which the samples were generated, such as adding new attributes to better represent sampling variability (Manor & Ben-Zvi, 2017). Similar extension have also been reported in other integrated modeling endeavors (Lehrer, 2017), however how these occur and how can these be then utilized to inform student's real world instigating inquiries has not been thoroughly examined. This may be in part due to the different visualization students employ when constructing the Sampler model, thus it is unclear how its extensions may manifest in its original real world representation. Therefore, we have chosen to focus on a specific representation first utilized in the preceding real world investigation but also employed during the subsequent probabilistic inquiry, and examine: *How can young learners repurpose a real world conjecture model and extend some of its features in a follow-up probabilistic inquiry?*

## Method

This study was conducted as part of the Connections project, a longitudinal design and research project (began at 2005) aiming at promoting young learners' statistical reasoning, in a technologically-enhanced and inquiry-based learning environment. We focus on the data collected in 2016 of a pair of second year participating 12 year-old students from a public school in Israel. Their entire sixth grade class participated in a 19 lesson long learning trajectory, which included three full (data and probability) investigation cycles. The students used TinkerPlots (Konold & Miller, 2015) to both create their data representations, as well as design a generative conjecture model and draw multiple samples from it. The findings we present in this article were taken from the second investigation cycle in which students were asked to make inferences about 1300 students of three schools in the district (including their school) based on a random sample of 60 students. Since our purpose was to learn more about the students' reasoning process employed to elucidate the role of a specific phenomenon, we chose to focus on an illustrative case study. We focus on the reasoning employed by a pair of academically successful students, Noa and Ido, second year participants in Connections. They were selected as they were verbal and communicated their reasoning openly and fluently, and exhibited a behavior observed in several other pairs while disclosing much about the reasoning that encouraged it: they utilized the same visualization in their

---

<sup>1</sup> The TinkerPlots Sampler allows students to design and run probability simulations, subsequently plotting the results to give a visual representation of the outcome over many samples (a sampling distribution).

inquiry of the real and probabilistic worlds. This facilitated us to more accurately examine how the same model was repurposed and what model features were subsequently extended.

All the activities and participants' actions were videotaped by three cameras during class discussion and Camtasia software to concurrently document the students' computer screen and articulations during their pair work. After transcribing all the pair's videos, the resulting data corpus was reviewed and analyzed according to the interpretative microgenetic method (Siegler, 2006), utilizing the RISM framework to translate the convoluted statistical modeling processes observed to discrete sets of well-organized snapshots (Dvir & Ben-Zvi, 2018). Key scenes and their transcripts, were discussed and triangulated (Schoenfeld, 2007) amongst the co-authors and a third Connections researcher.

## Findings

This section illustrates the progression of a specific model the pair had constructed during the second investigation cycle. Figure 2 illustrates the progression we will describe, from its first appearances during the real world investigation, to its development during the following probabilistic inquiry.

Figure 2: Illustration of repurposes and extensions of the medians model

### Initial use of the medians model: repurposing a real world data model to a conjecture model

The second investigation cycle focused on “sportiveness and gender”. Focusing on students’ 600 m running times, Noa formulated their research question: *Is the stigma that girls run slower than boys true?* The pair formulated an initial conjecture: “there is a small difference between boys [and girls, in favour of] the boys”, and began to investigate their real data by examining the 600 m results by gender (Figure 3). Asked by the researcher what can they see in the data, Noa replied:

Noa: That we [girls] do not run so well... 2 minutes and 5 seconds [miscalculation of the boys’ median – 165 sec] is not so good... [and the girls] run even worse. 2 minutes and 13 seconds [miscalculation of the girls’ median – 173 sec].

Figure 3: 600 m running times (seconds) by gender, colored according to grade

In response to the researcher's prompt, Noa described the median of each gender, and compared between them stating "[the girls] run even worse." This utilization of the medians, here representing what Noa *saw* in the data (her data model) is what we refer to as '*the medians model*', and its progression is what we will focus on throughout the Findings Section. The researcher, in accordance with the learning trajectory design, encouraged the pair to infer beyond the data, leading Noa to revisit her conjecture:

Noa: I think it [the population of 1300 students] will be less extreme than what I said. There would be a lot more boys than girls that will enlarge the median...

R: And who will be better, boys or girls?

Noa: Boys... I think that the boys' median will be a bit bigger and the girls median will be a little more bigger [means: smaller] ... by 1 [second]

The underlying behaviour of Noa's current conjecture (her abstract conjecture) had not strayed much from her initial conjecture ("there is a small difference between boys [and girls, in favour of] the boys"). The novelty, however, is the model *repurposed* to describe it, as for the first time the medians model is awarded this role. Furthermore, Noa also described here not only which of the medians will be "bigger", but also by how much – a new extension to the medians model. This implies that the data Noa expected her conjectured population to generate is rather specific. The extended feature of acknowledging the actual size (although not necessarily by number) of the difference between the two medians, will gradually take on a bigger role, reflecting a development in the pair's perception of the expected data.

### **Repurposing in the probability world**

During the remainder of the lesson, as well as the one that followed, the pair moved on to the next task of designing a generative model using the Sampler. Their model was based on both the real data sample as well as their perception of the running results of the population of 1300 students, thus reflecting their current conjecture: the girls' and boy results are almost equal, but boys run a little bit faster (Figure 4). After constructing the Sampler model, the pair began to generate simulated random samples from it. In the first sample drawn, the girls' median was significantly smaller than the boys' (Figure 5). Noa addressed this in multiple ways, for example, when the researcher introduced the boxplot in the following lesson. As the researcher asked the pair how the boxplot could be utilized, Noa replied: "We can see where there are more data, and also who is better, because if, for example our [the girls'] median is here [relatively small], and their median [the boys'] is here [larger] it means that we [the girls] are better here [in this sample]". Noa's response indicated that although the addition of the boxplot was an extended feature of the visualization, the underlying data model she was still utilizing is the medians model. Although now analysing a simulated sample, the role this model seemed to serve is similar to that in prior utilizations of the medians model: describe the data (a single sample) at hand. After drawing a second simulated sample, the researcher asked how the pair would like to compare between the samples.

Noa: Here too [in the second simulated sample as well as the first], we [the girls] are better [than the boys]

- R: Because of what?
- Noa: Because again [in another sample we see that] the [girls'] median is at better results and
- Ido: Why? But our [the boys'] median is becoming closer to yours [the girls' median]
- Noa: It is, but still [the girls' median is better than the boys']...
- Ido: It [the difference between the medians] is very similar, all the time...

**Figure 4: The Sampler model – the attribute on the left is gender and on the right, two “almost equal” distributions were designed for the boys’ (top) and girls’ (bottom) 600 m running times**

**Figure 5: Adding a boxplot to investigate the first simulated sample of the boys’ (top) and girls’ (bottom) running times in which the girls’ median is smaller than the boys’**

Noa began by stating the result of the comparison: “here too”. As the researcher prompted her to explain how she had ascertained this result, Noa referred again to the median as an indicator regarding who runs better. However, implied in her response is a possible extended feature: while comparing the medians (which is smaller – the boys’ or the girls’) served as a model for describing what the data in a single sample indicated (regarding who runs better), comparing which of the two medians is “better” across the two samples was a method to compare between the new simulated sample and the previous one. This *repurposing* was implied both by her use of “again” as well as the researchers’ question that instigated this exchange (how would they like to compare between samples).

Ido’s reaction introduced a new aspect, more explicitly addressing the new type of comparison (between samples, rather than between the two distributions within a single sample): comparing differences. Not only was he acknowledging the size of the difference between the two medians, as opposed to Noa’s acknowledging only which of the two prevailed, he was also explicitly focusing on the change that accrued between this current sample and the former: the boys’ median was “becoming closer” to the girls’, meaning the difference is now smaller. Despite Noa’s reply showing she did not consider the smaller gap between the two medians as a relevant indicator, Ido’s final statement takes this new aspect even one step further, as he used a much more general formulation: “all the time”. However, as the pair’s inquiry progressed the extended feature Ido had introduced was indeed picked up by Noa. An example for this can be seen in a later exchange:

- R: What will happen if we draw another sample?
- Noa: It seems to me it [the new sample] is the same. The boys [their median] are slowly slowly getting closer to us [to the girls’ median]

This last statement shows that not only was Noa now considering comparing the differences between the medians as a means of comparing the new sample with the previous samples, it is now even becoming a part of her newly forming conjecture. However, this conjecture does not reflect Noa's view of the real world phenomenon the pair were investigating (who runs better), rather a different kind of phenomenon: how much do samples such as those they were investigating vary? We therefore consider this to be a *repurposing* of the original medians model, here also serving as a conjecture model for the probabilistic phenomenon the pair were investigating.

The pair continued to generate more simulated random samples, and for each compared the difference between the boys' and girls' medians with the differences they saw in other simulated samples: "you [the boys' median] are getting closer to us [the girls' median] but it is taking you a lot of time" (Noa), "now it [the difference between two medians] is almost equal [to the previous difference]!" (Ido). The changes they observed varied, to the extent that in one sample, much to Noa's disappointment, the boys' median even surpassed the girls'. After several samples were drawn, the researcher prompted the pair to consider whether a sample size 60 can be trusted:

Noa: No, because let's say once they [the boys' median] can be here [at one point] and we [the girls' median] can be here [another point], and another time they [the boys' median] can be here [different point] and we [the girls' median] can be here [another different point]. It's confusing.

Ido: It [the difference between the medians] can always change.

Noa: Here [in other samples] it is like that they [the boys' median] slowly slowly closed [the gap] to us [the girls' median], and here [in one sample] they [the boys' median] are before us [is smaller than the girls' median].

Asked to evaluate the trustworthiness of samples size 60, both students responded by referring to the changes they had observed across the simulated samples: While Noa initially referred to variations in which of two medians prevailed, it seems that Ido was still focused on the difference between the two, reflected in his use of the singular form 'it' rather than the more appropriate 'they' had he been referring to the two medians. Nevertheless, Noa's final statement showed that she too was considering changes to the differences ("slowly slowly closed [the gap] to us"). Noa's depiction describes a range of possible differences between the two medians, a long way from her original expectation of one specific result (bigger "by 1"). The range of possible results is a key extended feature of the medians model, making it now much more statistical than its initial version.

## Discussion

Focusing on a specific model that emerged during the pairs' real world inquiry – the medians model – we sought to explore how the pair *repurposed* its goal and *extended* its features as they progressed in their inquiry and transitioned into the probabilistic follow up inquiry (Figure 2). As Noa and Ido designed their Sampler generative model to reflect their initial real world *abstract conjecture* (regarding running results), drawing multiple random samples from it allowed them to gradually explore its underlying probabilistic mechanism. Because they chose to repurpose the same visual representation (the medians model) rather than create a new one, they were both learning how the real world expected data would behave (or vary), and how this behavior would be portrayed in their

model (what can happen to the two medians). This indeed required extending some features of the original medians model, possibly as its original use (check each median and compare between them) was too complicated to track over several samples. The end result of this process was a much more elaborate and statistical model – one that serves the dual representative purpose in the real world investigation (both data and conjecture), and also is accompanied by a non-deterministic expectation regarding the data it can generate. Although the pairs' choice to repurpose a model they had used in their real world inquiry might appear coincidental or idiosyncratic, we have observed several other pairs chose to do the same. We attribute this to the IMA design: initiating the learning trajectory with a real world inquiry, and its close connection to the probabilistic follow up investigation. This case study illustrates how integrating a follow-up inquiry regarding probabilistic concerns that emerge from a real world investigation within an informal inferential setting can promote an important aspect of young learners' RISM: experiencing the population as a generative model, one from which various samples can be generated, and cultivating the learners' understanding that this variability needs to be examined and accounted for. In particular, repurposing the same models throughout both types of inquiry, can support reasoning with its underlying probabilistic mechanism.

# The role of decision-making in the legitimation of probability and statistics in Chilean upper secondary school curriculum

Raimundo Elicer

Roskilde University, Denmark; [raimundo@ruc.dk](mailto:raimundo@ruc.dk)

*Decision-making is argued to be intrinsically embedded in the historical emergence of probability and statistics, as well as in the justification for their inclusion as school mathematics subjects. In this article I investigate the role of decision in probability and statistics in both the current and upcoming Chilean upper secondary school mathematics curricula. Drawing upon Fairclough's model for Critical Discourse Analysis, I analyse selected texts as examples of broader discourse practices, in particular, I focus in assumptions, modalities, and intertextualities. They evidence the role of decision-making as legitimation of the subject matter and as a mediator of agency by teachers and students. I claim there is a shift towards less appeal to authority in legitimising the curriculum, and an increasing responsibility of students in the educational process.*

*Keywords: Critical discourse analysis, curriculum, decision-making, probability, statistics.*

## Introduction

As a scientific and mathematical field of knowledge, it can be argued that the history of probability and statistics is the history of making decisions when uncertain outcomes are to be evaluated. According to Hacking's (1975) historical and philosophical address, the notion of probability comes to answer whether a statement is an opinion or demonstrable knowledge during the middle ages. Later on the 17th century, probability, induction and statistical inference come to define the fair share when a gamble game is interrupted, whether an accused person is to be condemned, to decide the price of annuities and policy regarding pensions, and to take a stand about scientific hypotheses to be true or not. So risk and decision-making define the "logic" of probability (Borovcnik, 2015). Risk, as vague as this concept may be, is the way we evaluate decisions under uncertainty beyond the possible impacts of different choices, but also with some weight given to their likelihood. Probability comes to be an attempt to quantify these levels of likelihood.

As for probability and statistics as teaching-learning subjects, Pfannkuch (2018) has identified emerging curricular approaches to be addressed in future research. One proposition is to get "*more insight into fostering statistical argumentation* including learning how to make evidence-based claims in data-rich environments and critically evaluating data-based arguments in diverse media from a statistical literacy perspective" (p. 407, emphasis in original). This trend is grounded in research experiences focused in the complexity and scaffolding of decision-making tasks under uncertainty. Researching the 'critical lens' of decision processes would require different approaches such as action research, phenomenography, and critical discourse analysis (Petocz, Reid, & Gal, 2018, p. 81).

In this article I attempt to join both propositions by investigating the role of decision-making in current and upcoming probability and statistics official curricula, through a version of Critical Discourse Analysis [CDA]. In order to narrow down and have a sense of what is aim for regarding

students' future participation as citizens; I make an exemplary analysis that focuses in the Chilean last two grades of secondary mathematics school curriculum.

The general research questions addressed in this article are: (1) what is the role given to notions of decision-making in the Chilean upper secondary school probability and statistics curriculum? And (2) what has changed from the up-to-date version of the curriculum and the upcoming curricular framework for the same subject and grades?

Interpreting roles and spotting changes are broad intentions, so in the following section I address the conceptual framework and methods concerning a version of CDA, in order to understand these questions in a more precise way.

## Methodology

Inspired by Fairclough (2010), I am describing the methodology as an altogether analytical strategy, since “we cannot so sharply separate theory and method” (p. 234) while constructing the object of research. Starting with theoretical generalities, then I provide the necessary conceptual definitions that methods for selection and analysis require.

Fairclough (2010) defines a general methodology for critical research in an interdisciplinary way. In that line, the present discourse analysis dialogues with statistics education research. Key interrelated concepts are social structures, practices and events: “social structures define what is possible, social events constitute what is actual, and the relationship between potential and actual is mediated by social practices” (Fairclough, 2003, p. 223). In this frame language is a social structure. Among its infinite possibilities, choices are made to produce texts as part of social events, mediated by discursive practices, where discourse is understood as semiosis, i.e. the process of meaning-making.

My analytical strategy consists in selecting texts from the upper secondary school Chilean curriculum which refer to decision-making in probability and statistics, and then extracting elements of textual analysis which illustrate broader discursive practices. Textual analysis describes *what* is in the texts, and the discursive aspect addresses how these elements *give meaning*.

## Selection of texts

Chilean secondary education is defined from grades 7 to 12. These are called 7th-basic and 8th-basic, and from 1<sup>st</sup>-middle (9<sup>th</sup>-grade) to 4th-middle (12<sup>th</sup>-grade)<sup>1</sup>. All of these grades have their own study programs, but more general curricular frameworks are available for 7<sup>th</sup>-basic to 2<sup>nd</sup>-middle and the one for 3rd and 4th-middle is under construction. The text selection takes into account 3<sup>rd</sup> and 4<sup>th</sup>-middle curricula, and the aforementioned upcoming curricular framework, summarized in table 1.

For current versions of the curriculum, I will only take common plan programs, i.e. those directed to every student in the scholar system. Excluded programs are those differentiated mathematics studies

---

<sup>1</sup> Not to be confounded with middle school, as in between primary and secondary school. In Chile, *enseñanza media* (middle education) is the bridge between *enseñanza básica* (basic education) and *educación superior* (higher education).

defined for scientific education. Therefore, the texts are extracted from grades 3<sup>rd</sup>-middle and 4<sup>th</sup>-middle study programs.

Document	Label	Year	Curriculum	Author
Mathematics Study Programme, Third Middle	3M15	2015	2009	Curriculum and Assessment Unit, Chilean Ministry of Education (MINEDUC)
Mathematics Study Programme, Fourth Middle	4M15	2015	2009	
Curricular proposal for 3rd and 4th-middle: Public consultation document	34M17	2017	2018	

**Table 1: Sources of selected texts**

Study programs are divided into units (numbers, algebra, geometry, and data and chance). Within the units of data and chance, I look for sentences which make references to ‘decision’ (*decisión* in Spanish), including conjugations of the verb ‘to decide.’ These sentences will compose the texts.

The same selection applies the upcoming curricular proposal for these last two grades, within the mathematics subject. It does not still have the form of study programs, but it can be considered to be of the same genre, for it means to become the next version of such. It is a general proposal based on a process that involved national experts, international experiences and consultation to civil society participants. The document is published in MINEDUC’s website.

### **Data analysis**

The analysis is performed at two levels: textual and discursive.

Among the several possibilities for identifying and categorising elements in the texts, I will focus in three: modality, collocation, and intertextuality. Modality expresses a commitment the author does with truth and necessity, respectively by epistemic and deontic modalities (Fairclough, 2003, p. 165). It can be evidenced –nonexclusively– by the use of modal verbs, such as ‘may’ (epistemic) and ‘must’ (deontic). Collocation is the repeated co-occurrence of certain concepts, such as ‘hard working’ appears as a common binomial in political speeches. Intertextuality is the more or less explicit presence of elements of other texts and their authors’ voices. These elements can be dialogued with, assumed, rejected, and so on (pp. 41–42).

Beyond identification of modality, collocation and intertextuality in texts, I will point out the way they are chosen to be expressed as indicators of discursive practices. In particular, I focus in legitimisation strategies. Legitimation is the discursive practice of justifying what is made factual in the texts, through reference to authority, value systems or utility, or conveyed through narrative (Fairclough, 2003, p. 98).

Coming back to the research questions, I define the ‘role’ of decision-making as choices for the use of legitimisation strategies as discursive practices. Additionally, I shall identify changes from current to the upcoming version of the curriculum. Characterising this shift is the final stage of the analysis.

## Selected texts

As a way of organisation, Chilean study programs are divided into units. Each unit is described having purpose, previous knowledges, key concepts, contents, abilities, attitudes, expected learning outcomes (and their respective assessment indicators), didactical orientations, and suggested activities for each expected learning outcome. The following are the selected texts, and above them are the contexts within the study programs where they are found. All translations from Spanish are made by me as literal as possible.

In the 3<sup>rd</sup>-middle grade current curriculum (3M15), ‘decision’ appears in the form of ‘decision tree representations’, as a follow up for the goal of understanding the concept of conditional probability. I will not take it as part of the analysis, since it actually refers to ‘probability tree representations.’ Then it forms part of the general didactical orientations for the unit:

*3<sup>rd</sup>-middle. Unit 4: Data and chance.*

### *Purpose*

- 1 Experimental problems are worked with **decision** tree representations, which enable a bigger understanding of contents and a tool for probabilistic calculations. (3M15, p. 120, emphasis added)

### *Didactical orientations*

- 2 In this line, it is fundamental that the teacher promotes the development of random thinking, i.e. that students learn to make **decisions** with evidence in situations of uncertainty. (3M15, p. 123, emphasis added)

In the last grade current study program (4M15) there are actually two units about data and chance, with no mentions of ‘decision’ in ‘data and chance 2,’ which includes graphic notions about binomial and normal distributions. In ‘data and chance 1,’ ‘decision’ is part of the didactical orientations as in the 3<sup>rd</sup>-middle grade. Later on, there is a mention to ‘decision’ as a comment for teachers when engaging in activities for the learning goal to critically evaluates information:

*4<sup>th</sup>-middle. Unit 3: Data and chance 1.*

### *Didactical orientations*

- 3 In this unit, it is expected that students critically evaluate information published on the media and internet, from the analysis, interpretation and synthesis of such information, with which they can obtain results about a population considering its size and the variable’s distribution; infer conclusions from the mean, variance and standard deviation; and to make **decisions** grounded in statistically significant information. (4M15, p. 86, emphasis added)

### *Suggested activities*

- 4 Furthermore, it is important that the teacher promotes contextualized learning so students develop progressively the statistical literacy, which gives them tools for making grounded **decisions**. (4M15, p. 88, emphasis added)

As for the public consult document for the upcoming curricular framework (34M17), decision first appears as part of the general purposes of the mathematics subject:

*Mathematics: Formative purposes*

- 5 In order to achieve the latter, students will work collaboratively in mathematical modelling of situations, to make grounded **decisions** in disciplinary problems, as well as in the interdisciplinary, social, environmental or economic scope. (34M17, p. 49, emphasis added)

And then, utterances about decisions are part of mathematics learning goals in both grades:

*Learning goals for 3rd-middle*

- 6 [It is expected from students to be capable of] 3. Making **decisions** in situations of uncertainty, with information involving dispersion measures, double entrance tables and conditional probabilities. (34M17, p. 52, emphasis added)

*Learning goals for 4th-middle*

- 7 [It is expected from students to be capable of] 3. Solving problems in contexts of uncertainty, through the application of the binomial distribution and calculation of probabilities, for **decision**-making and critical analysis of statistical information. (34M17, p. 52, emphasis added)

Both learning goals have a parallel in the previous texts. In the current study programs (3M15 and 4M15), topics such as dispersion measures, conditional probabilities and the critical analysis of statistical information are covered.

## Textual analysis

I shall first identify and describe elements of textual analysis found in the excerpts as to provide input to the following discussion. I focus in modality, collocation and intertextuality.

### Modality

Modal forms expressed as ‘it is expected from/that students’ (3, 6 and 7) can be identified as epistemic modalities, i.e. as expressions of probability and truth, in this case, the expected and not certain to happen. It can be argued that, given the official character of curricula, these are actual expressions of the necessary, falling into the category of deontic modalities.

Explicit deontic modalities are evidenced as ‘it is fundamental that’ (2) and ‘it is important that’ (4), and they express necessity for particular promotions of the teachers in order to provoke students’ skills for making decisions.

### Collocation

References to decisions do not appear alone. A habitual co-occurrence of the substantive ‘decision(s)’ comes with ‘grounded’ as company; both as an adjective as in ‘grounded decision-making’ (4) and ‘grounded decisions’ (5), and as an adverbial form as in ‘decisions grounded in...’ (3). A similar adverbial accompanying form is ‘decisions with evidence’ (2) and ‘decisions with information’ (6).

This collocation suggests a reference to a particular type of decisions or decision-making processes, based on quantitative arguments, distinguishable from a mere act of making a choice.

### Intertextuality

Texts 2 and 4 can be read in parallel as having the same structure:

In this line, it is fundamental that the teacher promotes  the development of random thinking, i.e. that students learn to make decisions with evidence in situations of uncertainty. (2)	Furthermore, it is important that the teacher promotes contextualized learning so students develop progressively the statistical literacy, which gives them tools for making grounded decisions. (4)
----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

These texts make references to two different concepts, namely ‘random thinking’ (2) and ‘statistical literacy’ (4) in a similar way: as notions to be promoted by the teacher, implying students to make grounded decisions. So intertextuality is found within selected texts. Moreover, these concepts are not defined in the documents, but they are traces of another text published by the Chilean Statistics Society as experts’ curricular recommendations (Araneda, del Pino, Estrella, Icaza, & San Martín, 2011). The term ‘random thinking’ is not found in the literature, rather I presume the texts intend to refer to ‘statistical’ (Garfield & Ben-Zvi, 2007) or ‘probabilistic thinking’ (Chernoff & Sriraman, 2014). Both ‘statistical thinking’ and ‘statistical literacy’ are described as core answers to the section ‘Why teach statistics?’ (pp. 11–17) referencing a paper published in the International Statistical Review (Garfield & Ben-Zvi, 2007). Overall, texts 2 and 4 are referring to authority, introducing notions without further explanation, which are developed within national and international statisticians associations.

### Discussion: Discursive practices

Within Fairclough’s model, texts are part of social events, and they are signs of broader discursive practices. In the following I point out legitimization strategies evidenced by preceding elements of the textual analysis.

#### Legitimation

Making decisions appears as a way of justifying the teaching and learning of statistics in the curricula. The texts fulfil the purpose of not only saying what and how to teach and learn, but also why and for what. Fairclough (2003, p. 219) claims that much of the legitimization of a social order –such as the inclusion of particular knowledge in the official curriculum– is textual. In particular, the texts show three of the legitimization strategies identified by Van Leeuwen (2007), namely through mythopoesis, rationalisation, and authorisation.

Mythopoesis or legitimation conveyed through narrative is evidence by the collocation of ‘decision’ with ‘grounded’ (3, 4 and 5), and similar accompanying adverbial forms such as ‘with evidence’ (2) and ‘with information’ (6). This strategy is stable through the texts and makes the case for justifying probability and statistics, since not just any kind of decision is included, but only those rooted in data and mathematical rationality. It allows a steady association between such school subjects, and rational choice.

Merely associating probability and statistics to rational decisions is not enough, it is still necessary to justify the teaching. Aforementioned deontic modalities are evidence of legitimation through rationalisation, which refers to utility. Within the current curriculum (3M15, 4M15) teachers' promotions are 'fundamental' (2) and 'important' (4) for students to make grounded decisions. The upcoming proposal (34M17) provides a similar rationalisation in the form of 'in order to achieve the latter' and 'to make grounded decisions'(5), but this time it is mediated by the students' action, namely their collaborative work in mathematical modelling situations (5). In a way, this change represents another shift in the agency from teachers to students in the teaching-learning process.

I have already pointed out that traces of an authorisation strategy are found in texts from the current curricula (3M15, 4M15), through the inclusion, without further definition, of 'random thinking' and 'statistical literacy'. What is worth highlighting is the fact that this strategy is not found in the upcoming curricular framework (34M17). This shift resonates with the bottom-up nature of the latter document, where civil society plays a bigger role in the justification of curriculum. This alteration is coherent with another broader mention to 'decision' in the diagnosis chapter of the same document, where students "demand protagonism in decision making and aspire to contribute to solve problems in the world they live in, such as poverty eradication, climate change and sustainable development." (34M17, p. 13)

## Concluding remarks

Critical discourse analysis allows us to see texts as part of social structures mediated by discursive practices. In this article I analyse Chilean upper secondary school written curricula as evidence of legitimation strategies, showing that study programs not only describe what is to be taught, but also why. Decision-making appears as a key element of such legitimation, by establishing a narrative of probability and statistics linked to grounded, evidence-based and rational choice.

The analysis illustrates signs of change towards a justification which relies less in professional statisticians and educational researchers as authorities, and more into students' own learning activities as decision makers. This shift is part of the wish for a bigger role in decision processes which go beyond the disciplinary scope.

This article addresses a justification problem in mathematics education research (Niss, 1996). Future works should address whether it is possible connect decision-based motivations and curricular contents, and how this can be approached in teaching practice. Both possibility and implementation problems are part of the broader PhD project this article is embedded in.

This work was funded by the doctoral scholarship CONICYT BCH/DOCTORADO 72170530.

<sup>2</sup>Mary Immaculate College, University of Limerick, Ireland; [aisling.leavy@mic.ul.ie](mailto:aisling.leavy@mic.ul.ie)

*Recent approaches to statistics education situate the teaching and learning of statistics within cycles of statistical inquiry. This research focuses on the first step – the preparation of prospective teachers to pose statistical questions. We report on an investigation of prospective elementary teachers in Ireland (n=118) and Germany (n=40) as they design statistical questions. Support was provided through tutorials, think-pair activities, peer-feedback and expert-feedback. We describe the features of statistical questions posed, identify obstacles and difficulties experienced when posing questions and evaluate the effectiveness of both peer and expert feedback.*

*Keywords: Statistical inquiry, teacher education, primary teaching, posing statistical questions.*

## Introduction

A data analysis cycle such as the PPDAC (Wild & Pfannkuch, 1999) is a structure implemented in statistical inquiries across nearly all age levels. It consists of the phases: problem, plan, data, analysis and conclusion. The first phase, posing a problem (i.e., statistical question), is a critical prerequisite to stimulate a deep and rich analysis of data. It is also critical as the quality of the questions posed informs the types of data collected, determines the representations used and influences the interpretations that can be made. Arnold (2013, p. 19) makes an important distinction between two fundamental types of questions: investigative questions and survey questions. Investigative questions are “the questions to be answered using data” (p. 19), for example ‘What patterns are evident in social media use by teenagers?’ In contrast, survey questions are “questions which are asked to get the data” (p. 19), for example ‘How much time do you spend on social media at the weekend?’ One typical misconception is posing survey questions when being asked to pose investigative questions. We concentrate primarily on the generation and development of investigative questions (which we refer to as statistical questions). Our primary research questions are: What is the quality of initial statistical questions posed by prospective teachers and how does the quality develop across several phases (first version of the question, question revised after peer feedback, question revised after expert feedback)?

## Literature review

In the literature review we consider different types and categories of statistical questions. Biehler (2001) distinguishes between the number of variables included in statistical questions. An example of a one-variable question is: “What is the distribution of the variable height?” An example of a two-variable question is: “In which way do boys and girls differ in respect to the variable height?” For two-variable questions, Konold, Pollatsek, Well, and Gagnon (1997) distinguish between three different types. The first type, those investigating the relationship of two categorical variables (Are

boys or girls more likely to play handball?), are termed *categorical  $\times$  categorical*. Those investigating the relationship of two numerical variables (Is there a relation between hours spent on social media and school grades?) are termed *numerical  $\times$  numerical*. Questions in the *numerical  $\times$  categorical* category are referred to as group comparison questions - for example: “Do those with a curfew tend to study more hours than those without a curfew?” (Konold et al, 1997, p. 7).

These categories index descriptive features of statistical questions. A more evaluative approach is taken by Frischemeier and Biehler (2018) who have distinguished different qualities and developed a rating system for statistical questions. In this rating system, questions that take into account two variables are rated higher than those that take into account only one variable. In the subset of one-variable questions they distinguish questions leading to a yes/no answer (“Do 60% of the pupils have a mobile phone?”, p. 759), questions asking for a specific value (“How many pupils have a personal computer?”, p. 759) and more general questions referring to the entire distribution (“How is the variable “mobile phone” distributed?”, p. 759). In the subset of two-variable questions a similar categorization is made. Yes/No questions involving two variables are for example “Is there a difference between boys and girls in their time spent on computer use?” (p. 759) and questions aimed at working out differences in group comparison situations are for example “In which regard does computer use differ between boys and girls?” (p. 759). An example of a more sophisticated and complex statistical questions (called open and complex questions) involving two variables is “which differences exist between boys and girls in regard to their leisure time activities?”

Makar and Fielding-Wells (2011, pp. 349-350) provide specific characteristics of questions for statistical investigations such as “interesting, challenging, and relevant”, “statistical in nature” and “ill-structured and ambiguous” and Arnold (2013, p. 110-111) identified six fundamental criteria for what makes a good investigative question: (1) the variable(s) of interest is/are clear and available, (2) the population of interest is clear, (3) the intent is clear, (4) the question can be answered with the data, (5) the question is one that is worth investigating, that is interesting, that has a purpose, and (6) the question allows for analysis to be made of the whole group. For Criterion 1 this means that the variables are described in a clear way (with regard to the specific situation: summary, comparison, relationship) and have been correctly identified from the actual survey question. Criterion 2 focuses on the population of interest and whether learners focus on individuals, a sample or the population. Another important Criterion 3 is whether the question is clear with regard to whether it is a summary, comparison or relationship question (p. 111). Consideration of whether the question can be answered with the given data is tackled in Criterion 4. Criterion 5 deals with purpose and whether the information arising from answering the question is useful to someone. Finally, Criterion 6 investigates whether the question allows an analysis with regard to a local view (single points, single aspects) or a global view on distributions (characteristics like center, spread, skewness).

Empirical studies examining learners’ reasoning when generating statistical questions reveals that learners across all ages face problems generating adequate statistical questions (Arnold, 2013; Frischemeier & Biehler, 2018; Pfannkuch & Horring, 2004). In their work with secondary schools students, Pfannkuch and Horring (2004, p. 208) observed that students frequently forgot to look back to the original questions and use it to guide their discussion of the data. Switching focus to the

teachers, Pfannkuch and Horring (2004) stated that the “teachers tended to pose narrowly framed statistical questions according to a template” (p. 208). Frischemeier and Biehler (2018) investigated the development of the quality of statistical questions posed by primary preservice teachers while engaged in a PPDAC-cycle while enrolled in a course on statistical thinking. One fundamental conclusion of Frischemeier and Biehler (2018) was that the quality of a statistical investigation depends on the statistical question that was posed and subsequently stimulates the investigation. Thus poor statistical questions requiring only a yes/no answer or including only one variable, lead to short and non-sophisticated statistical explorations. Interestingly they concluded that despite the provision of feedback (peer and expert) during two stages of the study, the quality of statistical questions did not improve in a considerable way. Our study reported in this paper investigates how to support prospective primary teachers design statistical questions that motivate a cycle of statistical inquiry suitable for upper grade elementary children.

## Methodology

Irish participants ( $n=118$ ) were 3<sup>rd</sup> years in a 4-year undergraduate degree. They were enrolled in a 12-week compulsory module on the teaching of statistics and probability, the first 8 weeks focused on statistics. They were taught in groups of 30-40 students, once a week for 60 minutes (in Autumn 2017). German participants ( $n=40$ ) were 1<sup>st</sup> years in a 3.5-year undergraduate degree. They were enrolled in a 14-week compulsory course on the teaching of geometry and statistics (in winter term 2017/2018), the last three weeks focused on statistics. They met twice a week for a 90-minute lecture and a 60 minute seminar. Courses in both settings were designed around the cycle of statistical investigation which focused attention on the problem, plan, data, analysis and conclusion (PPDAC) components (Wild & Pfannkuch, 1999) and its’ implementation in primary classrooms. A core assessment task was the design of a statistical question that would stimulate and drive a cycle of statistical investigation targeted for use with upper elementary grade children (ages 10-12). The content and sequence of the courses was similar across settings and focused broadly on: designing statistical investigations (the PPDAC cycle), types of data, samples and populations, representing and analysing data distributions using graphical visualisations, calculating and interpreting summary statistics (measures of central tendency and variability), and comparing distributions of data.

## Study Design

This paper reports on the first part of the investigative cycle: *the design of statistical questions*. Following instruction on the cycle, participants were placed in pairs and informed that they would be required to design a statistical question, and an ensuing statistical investigation, which they would revise and develop over the course of the semester. The three-phase design consisted of:

*Phase 1 (Think):* Participants worked in pairs to design a statistical question (SQV1) that promoted comparison of two numerical data sets. Course content aligned with this phase, provided examples of strong and weak research questions and explored statistical components relating to question design. Phase 1 culminated with the design of the first version of the statistical questions (SQV1).

*Phase 2 (Peer-feedback):* Phase 2 provided peer feedback on initial questions. It was envisioned that providing and receiving feedback would develop skills in identifying desirable features of statistical questions. Each pair received the statistical questions (SQV1) of another pair and used a

set of criteria (developed by the authors, Table 1) to guide analysis and feedback. Pairs recorded feedback in the form of questions or statements which were then returned to the original pairs. Phase 2 culminated with participants presenting a revised statistical question (SQV2).

*Phase 3 (Expert-feedback):* The goal of phase three was the construction of the final research question (SQV3) based on the provision of ‘expert’ feedback to all participants. Expert feedback was provided during a plenum discussion and was generic in nature in that it identified the general shortcomings, strengths and desirable features that emerged in the revised questions (SQV2). Arising from the plenum, participants revised and improve their statistical questions (SQV3).

Look at the question	Is it meaningful? Will the question sustain interest and curiosity of primary children? Is the intent clear and unambiguous?
Think about the variables of interest	Is the variable described clearly? Is the variable available/possible to measure?
Look at the relationship between the question and the data it will generate	Can the question be answered with a simple “yes/no” response [avoid these type of questions]? Will the question generate quantitative data (i.e., numbers)? Will the question motivate a focus on two data sets? Does it promote group comparison of data?
Look at (or imagine) the data	Can you answer your question with the given data? Is there sufficient data collected to answer the question? Is there sufficient variability in data collected (is there the potential for a wide range of possible data values)?

**Table 1: Criteria used to provide feedback on statistical questions**

## Data & Data Analysis

The statistical questions at the phases SQV1-SQV3 constituted the data. Hence our analysis focused on these questions. We identified characteristics of questions posed, rated these characteristics and compared their quality across the three phases. A structuring qualitative content analysis method (Mayring, 2015) was used for rating statistical questions. We constructed our categories mainly using a deductive approach but also took into account inductive elements from our data as a kind of a “mixed approach” (as it is explained in Kuckartz, 2012, p.69). Due to the fundamental theoretical work (see especially Arnold, 2013) carried out on the generation of statistical questions (categories, criteria, etc.) we firstly and mainly used a deductive approach to use and adapt categories and constructs established from existing research studies (Arnold, 2013, Biehler, 2001, Frischemeier & Biehler, 2018, Konold et al. 1997).

The quality of statistical questions was determined using the four question components (Table 1) as an analytical frame. A structured rubric consisting of coding rules and key examples was developed and it carefully guided the assignment of a precise code to each question component. A development process was used to arrive at the components and their sub components (see Column 1, Table 2); however, its description is beyond the scope of this paper. For illustrative purposes, we

will focus only on the development process for the first component “Look at the question” since it considers general characteristics of statistical questions like *Question\_meaningful*, *Question\_interest*, *Question\_clear*, *Question\_variables* and *Pop\_interest*.

For instance *Question\_meaningful* considers whether the question is meaningful (connected to a context, e.g., “Do female students spend more time doing homework than male students?”) and *Question\_interest* examines whether the question is interesting for primary school students from an affective point of view (e.g., “Do children with pets spend fewer time with their friends than children without pets?”). Both categories are based on Arnold’s Criterion 5 (Arnold 2013, p. 111).

The category *Question\_clear* is based on the third criterion of Arnold (2013, p. 111) that “from the question it needs to be clear if it is a summary, comparison or relationship question”. Thus we determined whether each statistical question was posed in a clear and unambiguous way. A counter-example for a non-clear statistical question found in our data is for example “What is the probability that a boy in your class has glasses?” This sample question does not refer to a statistical investigation and is neither a summary nor a comparison or relationship question.

The category *Question\_variables* is based on the categorizations and work of Konold et al. (1997) and Biehler (2001). This category checks which kind of variables (categorical, numerical) are embedded in the statistical question and whether they are implemented in a single form (question with regard to a distribution of a single categorical or numerical variable) or as a combination in the statistical question (categorical vs. categorical, numerical vs. categorical, numerical vs. numerical).

The category *Pop\_interest* is based on Arnold’s (2013) second criterion (p. 111). In this category we are interested in the language used in the statistical question and whether the focus is on an individual case, on a sample or on a population. As also mentioned in Arnold (2013), the use of “a” (e.g., a boy) might indicate an individual focus, the use of “the” (e.g., the boys) might refer to cases in the sample and more general the use of “boys” might indicate a focus on a population.

## Results

**Looking at the question:** In Phase 1, the majority of questions posed were meaningful and of interest to children (Rows 2 & 3, Table 2); however, the clarity of these questions posed a greater challenge for Irish participants (see Row 4). Improved clarity was evident across subsequent phases indicating the benefit of peer and expert feedback. By the end of the study, the majority of Irish and Germans (90%, 85%) posed questions involving two variables. A greater number of two-variable questions were posed by Germans in Phase 1 (75%) compared to Irish (44%) (see Row 5, Table 2). Furthermore, the large number of two-variable questions posed in Phase 1 by the Irish (44%) remained stable in Phase 2 (42%) indicating that peer feedback seemed to have little immediate effect. Although there was less room for variation in the German cohort, there was also very little change across the phases. Similarly (see Row 6, Table 2), while the population of interest was clear in 90% of final research questions for both groups, Germans were more successful in identifying the population of interest in Phase 1 (75% versus 58%). The lack of clarity in Irish participants’ initial questions may have contributed to the lack of clarity in identifying the population of interest.

**Variables in the question:** Initially there was a lack of clarity in describing variables with less than 50% being successful in Phase 1 (see Rows 8 & 9, Table 2). For example, examination of the question (Pair 11, Germans) reveals the lack of clarity in the variable ‘sporting activity’ in terms of what will be measured and the units of measurement. The feedback phases were successful for both groups in improving the clarity of variables (see Pair 11 below). German participants still struggled for clarity in variable description at the end of the study as compared to their Irish counterparts.

Are there differences in the sporting activity of boys and girls? [Pair 11, SQV1]

Are there differences in the *weekly* sporting activities *in hours* of boys and girls? [Pair 11, SQV3]

**Relationship between the data and the question:** Exploring the relationship between the posed question and the data generated provided insights into how the question opened, or closed, opportunities for exploration of data. Compared with other categories, this category was quite stable over the three phases (see Row 11, Table 2). For both groups, the number of simple survey questions showed a small decrease across the phases. Correspondingly the number of more sophisticated questions showed small increases across phases indicating improvement in the quality of questions posed across the study. Examples of questions categorised as sophisticated in Phase 3 are below.

By how much do the shoes sizes of boys and girls in Class 5 differ? [Pair 3, SQV3, Irish]

Based on your examine of the sugar content of the fruit juices and minerals provided here, explain which drinks are more suitable for consumption. [Pair 1, SQV3, Irish]

**Looking at the data:** There was no requirement for German participants to submit data sets, hence we report only on Irish data for 3 of the 4 sub-components (see Rows 13-15, Table 2). In Phase 3, 95% were able to answer the question with the given data. Similarly, 95% collected sufficient data to answer the question. When the data sets were examined, the majority (92%) had sufficient structure or variability in the data (that means that a wide range of possible values are given). Both groups demonstrated a steady increase in questions that supported a global view across both phases indicating the benefit of both peer and expert feedback (see Row 16 in Table 2).

Component: Look at the question		Phase 1 (%)	Phase 2 (%)	Phase 3 (%)

## Discussion

When provided with appropriate structured support, prospective teachers can develop the skills and understandings to develop rich statistical questions. However, developing good statistical questions is particularly complex and requires considerable support. Multiple considerations are required. *Question* considerations require attention to the meaningfulness, interest, and clarity of questions in addition to the variables and populations elicited by questions. Consideration of the *variable* requires attention to the clarity of the variables described and the measurement of those variables. Consideration of the *relationship* between the question and the type of data generated is also required in an effort to ensure the data support subsequent analysis. Finally, the *data themselves* require consideration. Attention must be paid to the ability to answer the question from the amount and type of data generated, whether there is sufficient variability in the data and that the question supports a global view of the data. It is not surprising that some of these categories posed lesser or greater difficulty. While participants showed great expertise in addressing the meaningfulness and interest of questions and in identifying the variables available to measure, in contrast, all participants struggled initially to provide clarity when describing the variables. While the purpose of the study was not to compare the Irish and German participants, it is noticeable that German participants performed better across many of the categories in Phase 1. It appears that Irish participants invested their energies in the broader contextual dimensions of questions and in framing questions resulting in the relative neglect of the necessary statistical and content dimensions of the questions posed. The benefits of the peer-feedback process (Phase 2) are not clear from this study. On the one hand by comparing performance across Phases 1 and 2, peer review

brought about improvements in some aspects of question design. It appears to have supported the revision and improvement of some question aspects, most notably in clarifying the question and in identifying the population of interest. For other components, peer-feedback did not seem to support any substantial gains in question quality particularly when selecting and identifying the number of variables embedded in the question and in bringing about improvements in the question type. The effect of feedback when generating and developing statistical questions needs further research into the future.

# Investigating teachers' pedagogical content knowledge for statistical reasoning via the real life problem scenario

Rukiye Gökce and Sibel Kazak

Pamukkale University, Denizli, Turkey; [rukiyegokceimt@gmail.com](mailto:rukiyegokceimt@gmail.com)

*The aim of this case study is to identify the levels of pedagogical content knowledge (PCK) of middle school mathematics teachers in relation to statistical reasoning through a real life problem scenario. In this paper we focus on nine teachers' PCK about student thinking and misunderstanding in the context of Leukemia problem scenario. The data from the interviews were analyzed qualitatively. The results indicate some inadequacies in teachers' knowledge of student thinking and misunderstandings with regard to statistical reasoning.*

*Keywords: Statistical reasoning, pedagogical content knowledge, knowledge of student thinking, knowledge of student misunderstanding, middle school mathematics teachers*

## Introduction

Statistics is a methodological discipline for dealing with data (Moore & Cobb, 1997). Statistics also has an important role in critical and creative thinking in solving real life problems using data. Individuals who can use statistical knowledge while solving real life problems can be effective citizens. Therefore, using real life problems in teaching statistics is important to prepare individuals to cope with the challenges of daily life more easily. Because a lot of difficult statistical calculations can be made easily by technology, these skills require knowing how statistical information is to be used, analyzed and interpreted, and how to make inferences based on data. Hence it is important that individuals develop their statistical reasoning skills in order to be able to cope with the statistical information surrounding them in daily life. Statistical reasoning is defined as the way in which people reach the correct results from the statistical ideas and make sense of the statistical information (Garfield, delMas & Chance, 2003). Individuals' statistical reasoning skills can be improved during their school education (Garfield & Ben-Zvi, 2007). Teachers play a key role in developing the statistical reasoning skills of students and encouraging them to use these skills. So, teachers need to be well equipped to help students develop such skills. However, the earlier studies (Burgess, 2007; Callingham & Watson, 2011; Madden, 2008; Sorto, 2004; Watson, Callingham & Donne, 2008; Watson, Callingham & Nathan, 2009; Watson & Nathan, 2010) suggest that teachers do not have adequate knowledge of statistics and teaching statistics. Hence, teachers' knowledge about statistical reasoning and how they focus on students' statistical reasoning in teaching statistics become a needed area of inquiry. The purpose of this research is to examine the levels of pedagogical content knowledge (PCK) of nine middle school mathematics teachers with regard to statistical reasoning within the context of a real life problem scenario.

## Theoretical Framework

PCK is one of the seven categories of knowledge that a teacher should have in order to make subject matter knowledge accessible to learners (Shulman, 1987). Literature on PCK identifies the knowledge

of student understanding specific to subject matter as one of the sub-dimensions (Ball, Thames, & Phelps, 2008; Shulman, 1986). Burgess' (2007) study on teacher knowledge in teaching statistics showed that teachers were inadequate in using knowledge dimensions that could enrich learning and thus potential learning opportunities were missed. These missed opportunities were related to the following themes in relation to teacher knowledge about teaching statistics: familiarity with the data, interpreting student thinking, student difficulties related to statistical inquiry cycle, understanding of variation, and understanding the development of informal inference.

Callingham and Watson (2011) pointed out the importance of identifying the PCK of teachers in advancing students' statistical understanding. In their study they identified the levels of 42 teachers according to their PCK performances as follows: Aware Level, Emerging Level, Competent Level and Accomplished Level. Teachers at the aware level had less comprehensive statistical understanding and could not make appropriate recommendations to guide student understanding. The classroom interventions proposed by the teachers at the emerging level were, in particular, largely in the form of general strategies. These suggestions were not exactly in the context of statistics, but they pointed to a good teaching. Teachers at the competent level proposed statistically appropriate interventions only in the context of class activities they were familiar with. Teachers at the accomplished level were able to suggest appropriate or inappropriate student responses and student-centered intervention strategies combined with appropriate statistical content.

Watson, Callingham, and Nathan (2009) identified four non-hierarchical components of PCK in a study examining teachers' pedagogical content knowledge in statistics at the middle school level. The first two components that are "recognizing big ideas" and "anticipating student responses" reflect the link between teachers' content knowledge and knowledge of understanding of student thinking. The last two components, "employing content-specific strategies" and "constructing shift to general", include pedagogical practices used by teachers foreseeing the development of student perspectives.

Shulman (1986) and Ball, Thames and Phelps (2008) point to the importance of teacher knowledge of student. Also Burgess (2007), Watson, et al. (2009) and Callingham and Watson (2011) suggest that teacher knowledge needs to be researched more in depth and systematically in statistics education literature. On the other hand, the statistics education literature contains little research on teacher knowledge particularly with regard to statistical reasoning. Thus, this study focuses on investigating the levels of middle school mathematics teachers' PCK related to statistical reasoning.

## **Method**

The case study method was used in the study. The participants of the study consisted of nine middle school mathematics teachers (two female and seven male teachers) from two different schools who volunteered to participate in the research. The participants' years of teaching experience varied between 2 and 35 years. As the interview is the most common data source in case studies (Yin, 2012), data for this study were collected through one-to-one interviews with participants using audio and video recordings. The unit of analysis was teachers' expressions used for each PCK dimension.

## Data collection and task

A classroom discussion scenario about the leukemia problem was used during the interviews. The leukemia problem was inspired by the AIDS problem in the study of McClain, Cobb, and Gravemeijer (2000). As shown in Figure 1 the problem requires a comparison of two data groups with different sizes to decide whether the new treatment is more effective than the traditional one in decreasing the number of white blood cells within the given context related to leukemia.

**Figure 1: Data given in the Leukemia Problem in the interview protocol**

In order to develop the classroom discussion scenario, the leukemia problem was firstly administered to the 6-8<sup>th</sup> grades students to get a wide range of responses. Then the dialogue in Figure 2 was developed using these students' reasoning. In the interview, teachers were asked to identify which students used appropriate and inappropriate reasoning and the difficulty that might prevent the student from reasoning in an appropriate way.

- 1 **Teacher:** What can you say about whether the experimental treatment used on 65 leukemia patients is more successful than the traditional treatment used in 215 leukemia patients or not?
- 2 **Didem:** I am thinking that traditional treatment is more successful. Because the most people do not want to use the newly developed treatment method.
- 3 **Aylin:** I agree with you, Didem. Number of white blood cell of 43 of the patients treated with the experimental method is between 7000 and 25000. In a drop of blood of 59 of the patients treated with the traditional method there is 7000-25000 white blood cell. Traditional methods have improved more patients. I am thinking that traditional method is more successful, too.
- 4 **Teacher:** Ok then, Tuğçe?
- 5 **Tuğçe:** I think we must consider the traditional method of its own and experimental method of its own, too. 59 of the 215 patients in the conventional treatment and 43 of the 65 patients in the experimental treatment improved. But I don't know how to compare these.
- 6 **Teacher:** What do you think, Kağan?
- 7 **Kağan:** I think that the experimental method is slightly more successful. Because in the experimental method there is no patient in the most high cell values. However, in the traditional method most of the high values of cells are filled. Only in the number of cells 45 thousand, 51 thousand, 52 thousand, 53 thousand and 55 thousand there is no patient.
- 8 **Teacher:** Ok then, is there anybody thinking differently? Sinem?
- 9 **Sinem:** Teacher, I think experimental method is more successful. Because 215 is 3 times 65. If we equalize them, in the experimental method 43, in the traditional method approximately 19 people's white blood cell values return to normal.
- 10 **Hale:** Teacher, it is clear from the shape of the graph. The experimental method is more successful.

- 11 **Teacher:** How did you get that from the shape of the graph, Hale? Can you explain it?
- 12 **Hale:** In the traditional treatment most of the patients stacked on the right side of 25 thousand, in the experimental method most of the patients stacked to the left of the 25 thousand. In the experimental method the number of cells in most patients fell below 25 thousand.

**Figure 2: The dialogue between students and teacher about the leukemia problem**

### Data analysis

In the data analysis, along with the content analysis, the levels of statistical reasoning were defined using the framework and PCK levels used in Callingham and Watson (2011). Codes for PCK dimensions were defined by adapting Watson and Nathan's (2010) codes for statistical reasoning. These codes defined by the levels and PCK dimensions are shown in Table 1.

	Student Thinking		Student Misunderstanding	
	Codes	Explanation	Codes	Explanation
Inadequate Level	No identifying	No explanation	Failure to explain student misunderstanding	No explanation
	Wrong classification	Classifying inappropriate student reasoning as appropriate or classifying appropriate student reasoning as inappropriate	Wrong answers	Identifying misunderstanding incorrectly due to the earlier misclassification of student reasoning
Aware Level	Irrelevant identifying	Expressions different from the answer given by the student	Irrelevant student misunderstanding	Expressions different from the possible misunderstanding of the student
	Identifying based on personal belief	Expressions based on such reasons as carelessness	Student misunderstandings based on personal belief	Expressions based on such reasons as carelessness
	Correct classifying based on wrong reasons	Explanations consisting of classification for wrong reasons	Determining student misunderstandings based on wrong reasons	Identifying student misunderstandings based on wrong reasons
Emerging Level	Uncertain identification	Statements not consisting of clear explanations and repeating the student's response	Uncertain answers	Statements not containing clear descriptions regarding the source of the error/misunderstanding and repeating the student's response
	Incomplete reasons	Insufficient explanations for the reason	Incomplete answers	Insufficient explanations for the source of student error
	Reasons not including clear specific details in relation to the case	Statements based on general statistical interpretations and lack of student knowledge	Responses not including clear specific details in the relation to the case	Statements based on general statistical interpretations and lack of student knowledge

Competent Level	Accurate reasons	Accurate classification of student reasoning based on correct reasons	Accurate reason for student misunderstanding	Explaining the source of student misunderstanding leading to inappropriate statistical reasoning based on correct reason
-----------------	------------------	-----------------------------------------------------------------------	----------------------------------------------	--------------------------------------------------------------------------------------------------------------------------

**Table 1: Codes for each level and two PCK dimensions: student thinking and misunderstanding**

## Findings

### Teachers' PCK levels with regard to student thinking

Teachers' success rate for identifying appropriate and inappropriate student reasoning in the given dialogue and the PCK levels based on their explanations regarding student thinking are shown in Table 2. In the leukemia problem scenario teachers have identified six examples of student reasoning as appropriate or inappropriate. The success rate in Table 2 is calculated by the ratio of the number of correct identifications to the number of all student reasoning responses. The purpose of calculating this ratio is to be able to determine the adequacy of teachers in distinguishing appropriate and inappropriate examples of statistical reasoning. Even though several teachers had the same success rate of 67%, as seen in Table 2 the quality of their explanations varied according to the PCK levels described in Table 1.

	Success Rate	Inadequate Level	Aware Level	Emerging Level	Competent Level
Ebru	67%	2	-	-	4
Suat	67%	2	-	1	3
Ismail	50%	3	2	-	1
Güven	83%	1	-	-	5
Eren	17%	5	1	-	-
Semih	67%	2	-	-	4
Seda	67%	2	-	-	4
Orhan	67%	2	-	-	4
Okan	67%	2	-	1	3

**Table 2: Teachers' success rates and the number of responses at each PCK level related to student thinking**

While the teachers' success rates of correctly identifying students' reasoning change between 17-83%, there are only two participants with a success rate of 50% or less and other success rates are close to each other except for the lowest and highest success rates. In addition, the teachers' statements for the reasons of classifying student reasoning examples are either inadequate level or competent level. This can be related with teachers having more knowledge about some reasoning approaches than the others.

One example of inadequate level was the explanation of Ismail teacher, who considered Aylin's reasoning (Figure 2, statement 3) inappropriate and explained her reasoning as "*there is no need for the new one [treatment], I think she wants to say that it can be carried like that [traditional]*". This

response was considered at the inadequate level because it consisted of details that were not relevant to Aylin's reasoning approach.

Eren teacher classified Aylin's reasoning approach as inappropriate. He explained his reason as "*She has taken into account the number of healthy people. I mean, she did not take into account the entire treatment period.*" The teacher's explanation was evaluated as a response based on incorrect reasons and considered at the level of aware.

Suat teacher who stated that Aylin's reasoning approach was not appropriate, explained his reason as "*She did not consider the patients who were out-of-range.*" Suat teacher's description did not include details on how to handle the number of patients outside the range. For this reason, his answer was dealt with at an emerging level because it did not contain specific details.

The reasoning of Sinem (Figure 2, statement 9) was classified as appropriate. Because Sinem took into account the difference in the sample sizes while comparing two distributions and used proportional reasoning. Güven teacher stated that Sinem used a suitable approach because she equalized the number of data in the groups using proportions. For this reason, the explanation of Güven teacher was evaluated as a correct answer and considered at the competent level.

### Teachers' PCK levels with regard to student misunderstanding

Teachers' success rate for identifying the difficulties causing to inappropriate student reasoning in the given dialogue and the PCK levels based on their explanations regarding student misunderstanding are displayed in Table 3.

	Success Rate	Inadequate Level	Aware Level	Emerging Level	Competent Level
Ebru	50%	2	1	-	1
Suat	50%	2	1	-	1
Ismail	50%	2	2	-	-
Güven	75%	1	-	-	3
Eren	25%	3	1	-	-
Semih	50%	2	-	-	2
Seda	50%	2	-	1	1
Orhan	50%	2	-	1	1
Okan	50%	2	-	1	1

**Table 3: Teachers' success rates and the number of responses at each PCK level related to student misunderstanding**

As seen in Table 3, the teachers' success rates of correctly identifying the difficulties causing to inappropriate student reasoning change between 25% and 75% and it is mostly at 50%. Moreover, the teachers' explanations about the sources of the errors are generally at the inadequate level and some at the competent level. Two of the teachers could not respond at the competent level. These findings point out the inadequacy in teacher knowledge about student misunderstanding.

Ismail teacher considered Kağan's inappropriate statistical reasoning (Figure 2, statement 7) as appropriate: *"Kağan used appropriate reasoning because he took both data groups into account and compared the data"*. Therefore, the explanation of Ismail teacher was evaluated as a wrong answer and considered at the inadequate level.

Ebru teacher explained Aylin's misunderstanding as *"Rather than evaluating the information at hand, she made a decision according to her own ideas or her thoughts based on observations around her."* While Ebru teacher considered Aylin's reasoning as her personal opinions, she did not notice that Aylin failed to take into account the number of data points in each group and did not mention the lack of proportional reasoning. Therefore, the explanation of Ebru teacher was evaluated as an irrelevant answer and considered at the aware level.

Orhan teacher made a statement about the misunderstanding behind Aylin's inappropriate reasoning: *"I think the difficulty is that she cannot understand the text and the question exactly."* His explanation indicating that *"she does not understand the question"* was evaluated at the aware level because it was mainly an expression that showing an evaluation based on a personal belief.

Seda teacher explained Aylin's error as *"Inability to fully understand the logic. For example, when there are two data [groups] to compare, she cannot specify the method of comparison."* Since her explanation did not specify the point about how to determine the method of comparison, her statement was evaluated as an uncertain response and considered at the emerging level.

Güven teacher stated that Tuğçe's reasoning (Figure 2, statement 5) was in an inappropriate form and explained her misunderstanding as *"she cannot see the ratio between the values and cannot calculate"*. Güven teacher's explanation was considered at the competent level because he based the source of the error on the right reasons.

## Discussion and conclusion

The results of this research show that participating middle school mathematics teachers tend to have difficulties in recognizing the appropriateness of student reasoning. We did not see any pattern in teachers' success rate of identifying which students used appropriate and inappropriate reasoning with regard to their years of teaching experience in this study. This could be due to the small number of participants volunteered for this study. Moreover, teachers PCK levels with regard to student thinking and misunderstanding are either insufficient or competent. These findings suggest that while teachers are better in recognizing some students' reasoning approaches, they have no knowledge about some others. Therefore, teachers need to develop a spectrum of student thinking knowledge about statistical reasoning. Inadequacies in teachers' knowledge of student are similar to the findings of earlier research (Callingham & Watson, 2011; Watson & Nathan, 2010; Watson, et al., 2008). As Shulman (1986; 1987) and Ball, Thames, and Phelps (2008) point out, student knowledge is one of the important dimensions of the PCK. According to Burgess (2007), such inadequate knowledge can lead to the missed opportunities for developing student learning. However, we were not able to analyze this since the teachers were not observed in the actual classroom for a long period of time. For future research, both interviews with teachers and lengthy classroom observations can be conducted to gain deeper understanding of teachers' PCK in relation to student thinking and misunderstanding.

## ***It's a good score! Just looks low: Using data-driven argumentation to engage students in reasoning about and modelling variability***

Orlando González<sup>1</sup> and Somchai Chitmun<sup>2</sup>

<sup>1</sup>Assumption University, Graduate School of Human Sciences, Bangkok, Thailand; ogonzalez@au.edu

<sup>2</sup>Teppleela School, Bangkok, Thailand; schitmun@hotmail.com

*This paper describes senior high school students' different ways of reasoning about and modelling variability, drawn from the initial phase of an ongoing study. A group of 26 Thai Grade 12 students was engaged in a statistical investigation by addressing a socially open-ended problem based on an unsorted set of varying test scores. Through engagement with this problem, students were able to experience data-driven argumentation and data modelling. From analyzing the answers provided by participants, four different categories of reasoning about variability (i.e., value-relation, magnitude-comparative, proportional, and distributional reasoning) and 11 ways of modelling variability in the context of the given situation were identified. The study also revealed that participants are somehow good proportional reasoners in general, but weak distributional ones.*

*Keywords: Argumentation, socially open-ended problems, reasoning about variability, variability modelling, statistical investigations.*

### **Introduction**

Good citizenship requires being statistically literate. Statistical literacy includes making sense of real-world data, the use of evidence-based arguments and critically evaluating data-based claims (Garfield & Ben-Zvi, 2008). Being critical is essential as claims and arguments are usually presenting selective information to convince another person to adopt or reject a specific point of view (Gal, 2004). On this regard, it has been reported in the literature that data-driven argumentation—which requires using, revising, manipulating, structuring and representing data to explain or persuade others—is very important for data modelling and informal inference (Garfield & Ben-Zvi, 2008; Shaughnessy, Ciancetta, & Canada, 2004).

Such importance has been acknowledged by recent reforms to the mathematics curriculum in many countries, Thailand being an example. In fact, according to the current Thai Basic Education Core Curriculum (MOE, 2008), Grade 12 graduates must be able, among other things, to analyze data and apply the results to express views and persuasive arguments using accurate and appropriate language. However, teacher's guides do not include specific instructional suggestions on this matter.

Under this scenario, socially open-ended problems (Shimada & Baba, 2015) emerge as an appealing and plausible way of providing students with the possibility of using, handling and interpreting data to inform argumentation and decision-making. This kind of problem has been reported as an instructional way to challenge students to structure variability among repeated observations of the same event, to model variability, and to engage in data-driven argumentation (González & Chitmun, 2017). The purpose of the present paper is to answer the following research question: what are the ways, if any, by which Thai senior high school students reason about and model variability, when they are asked to provide persuasive explanations and arguments based on data analysis, in the

context of a socially open-ended problem? A lesson implementation of a socially open-ended problem will be discussed and analyzed, and some conclusions will be given based on its results.

### **Practicing data-driven argumentation as advocacy**

Argumentation refers to discourse for persuasion, logical proof, and evidence-based belief, and more generally, discussion, in which there is reasoning on data, doubt about a standpoint or a disagreement with it, and frequently a question about whether, or at least why, a standpoint is worthy of acceptance (Blair, 2003; Garfield & Ben-Zvi, 2008). Argumentation can take two forms: inquiry and advocacy (Toulmin, Rieke, & Janik, 1984, as cited in Watson, 2018). The practice of argumentation as inquiry presupposes the act or process of deriving conclusions from data, whereas the practice of argumentation as advocacy presupposes the questioning of a standpoint, objections to a person's arguments, and arguments against the standpoint a person is supporting (Blair, 2003). Involvement with statistics in daily life is often about judging claims and arguments of others who practice statistics to some degree or another (Gal, 2004; Watson, 2018). Therefore, arguing against claims made by others (e.g., "your mathematics test score was awful!") is likely to require data-driven argumentation associated with advocacy. This involves the ability to advocate against the claim at hand with some evidence grounded in data, in order to make an alternate claim (Watson, 2018).

### **Statistical investigations and data-driven argumentation**

A statistical investigation is a process comprised of the following five phases: Problem, Plan, Data, Analysis, and Conclusion (PPDAC), regarded as one of the four central dimensions of statistical thinking used in statistical inquiry of real-life problems (Makar & Fielding-Wells, 2011). By engaging in statistical investigations, students are able to fully experience statistical processes such as acknowledging, modelling of and reasoning about variability, data representation, data reduction, data-driven argumentation, decision-making, and informal inference (Watson, 2018).

In order to appropriately conduct statistical investigations in the mathematics classroom, teachers and students need to use problems worthy of investigation, which involve statistical questions, a real-life context, and the following traits: (1) interesting, challenging, and relevant; (2) statistical in nature; and (3) ill-structured and ambiguous (Makar & Fielding-Wells, 2011). Addressing questions with these characteristics demands critical thinking skills and the practice of argumentation as advocacy, because questions developed for statistical investigations usually challenge and question, ambiguously or without proper statistical foundation, the standpoint a person is supporting (Blair, 2003; Gal, 2004; Watson, 2018). Thus, undergoing a statistical investigation requires the ability to challenge statements made in the given context and advocate, with evidence, for an alternate claim (Watson, 2018); in other words, requires the practice of data-driven argumentation as advocacy.

### **Socially open-ended problems as a trigger for data-driven argumentation**

Socially open-ended problems (Shimada & Baba, 2015) are problems embedded in a real-life context, familiar to the students and, by extending the traditional open-ended approach (Becker & Shimada, 1997), have been developed to elicit and address students' mathematical values (e.g., visual appeal, parsimony, abstraction, systematic reasoning), social values (e.g., compliance with the law, fairness, compassion, equity), and personal values (e.g., persistence, integrity, friendliness) through modelling

and argumentation. So, from the past section, it is possible to identify clear similarities between socially open-ended problems and the problems developed for statistical investigations.

In order to ensure triggering data-driven argumentation through the use of socially open-ended problems, the real-life context in which the problem is embedded must be statistical in nature (i.e., must enable students to collect, represent, reduce and/or interpret data to address a statistical question and reach reasonable conclusions under uncertainty; González & Chitmun, 2017). Thus, arguments from addressing the posed problem will have the four building blocks to make a good argument (Blair, 2003; Garfield & Ben-Zvi, 2008, p. 275): (1) A clear claim (and a counterclaim) we are making and/or anticipating; (2) data to support our argument; (3) evidence that the data are accurate and reliable, and (4) a good line of reasoning connecting the data to our argument.

The purpose of this study was not only to engage students in data-driven argumentation, but also to challenge them to reason about and model variability. To that end, the problem should provide students with opportunities to display, structure and model variability among observations of the same event, to make accessible and meaningful to students characteristics of distribution (e.g., center, shape and spread; Lehrer & Schauble, 2004; Mulligan & English, 2014; Petrosino et al., 2003).

## Research methodology overview

### Participants

On August 31, 2018, data were collected from a Grade 12 mathematics class (17- to 18-year-old youths) in a large public high school in Bangkok. The second author was the classroom teacher. A total of 26 students (boys=3, girls=23) were administered the task shown in Figure 1.

### Protocol and data gathering procedure

The task chosen for this study was an adaptation of the “Let’s think of an excuse for the test score” problem (Tamaoki, 2014, p. 120, see Figure 1). This task, a socially open-ended problem, requires from students to put in practice data-driven argumentation as advocacy, because they have to consider the variability in the given empirical distribution of scores and then generate additional arguments to explain Malee’s mother why her test score is not necessary such a bad result in the given context.

LET’S THINK OF AN EXCUSE FOR THE TEST SCORE										
The numbers below are the results achieved by a certain class on a mathematics test (100 points maximum), sorted by student number in the class attendance sheet. Malee is the only one who got 33 points. Only by what this score tells, she will be scolded by her mother. What could Malee possibly say to avoid a scolding for her mathematics test score?										
25	28	45	44	41	28	58	88	100	21	28
16	50	50	45	<b>33</b>	21	22	24	25	26	28
30	45	28	23	25	22	77	100	26	58	26
14	12	69	28	18	53	100				

**Figure 1: Task used in this study (adapted from Tamaoki, 2014)**

This task was collected from a Japanese junior high school teacher during a previous study conducted by the authors (González & Chitmun, 2015). In order that Thai students were able to respond to this task without being distracted by names or contexts unusual or non-existent for them, two changes

regarding the general cultural context were made when translating it into Thai: a Thai name for the student and “her mother” (as opposed to “her family” in the original task) were chosen for this version. The adapted task was then printed on single paper sheets and distributed among the students, who individually engaged in solving it after being instructed by the teacher. Fifty minutes were given to complete the task. Students were not assisted in any way that could influence their responses.

### Analysis of the collected data

Both authors used open coding and descriptive coding to analyze the information provided by the students, and to group similarly-structured answers into categories for analysis. After consensus between the authors, this process led to four categories on students’ reasoning about variability in the given task. Also, students’ ways of modeling variability were categorized. The authors also agreed on the placement of all the 26 responses into the categories previously created.

## Empirical findings and discussion

### Participants’ types of reasoning about variability

Students’ reasoning about variability fell into four coding categories: value-relation, magnitude-comparative, proportional, or distributional reasoning. Table 1 shows the percentages of students under each of these categories. Students were allowed to provide more than one argument to present Malee’s low test score as not such a bad result, resulting in a total percentage of more than 100%.

Category of reasoning	Description	%
Value-relation	Arguments using only comparative or ordinal phrases to indicate the difference between Malee’s score and particular data values within the data set.	46.2
Magnitude-comparative	Arguments using both comparative phrases (e.g., “greater than”, “less than”, “more”, “less”) and quantified expressions (e.g., “7 points”) to indicate the difference between Malee’s score and particular data values within the data set.	7.7
Proportional	Arguments using, implicitly or explicitly, the ratio, the actual percentage or the proportion of elements having a particular characteristic within the distribution of outcomes.	100
Distributional	Arguments combining two or more key features of the distribution of outcomes (e.g., centers, shape, skewness, density, outliers, and spread/variability).	15.4

**Table 1: Percentage of students using each coding category in this study**

Students whose responses included arguments using only comparative (e.g., “greater than”, “less than”, “more”, “less”) or ordinal (e.g., “third”, “fourth from”) phrases to indicate the difference or position between Malee’s score and either some center (i.e., the mean or mode) or a particular data value serving as reference point (e.g., 100 points), fell into the *value-relation reasoning* category. A total of 12 students (46.2%) fell into this category. The next quotes illustrate this category.

Student 20: The mode was 28 points. Malee’s test score is higher than the mode.

Student 26: I got 33 points, which is the 6<sup>th</sup> best score among all the students who failed the test.

Students whose responses included arguments using both comparative phrases (e.g., “greater than”, “less than”, “more”, “less”) and quantified expressions (e.g., “7 points”) to indicate the difference between Malee’s score and either some measure of center (i.e., the mean or mode) or a particular data value serving as reference point (e.g., 50 points), fell into the *magnitude-comparative reasoning* category. Only 2 (7.7%) out of 26 students fell into this category. Examples of this category follow:

Student 14: Malee got 33 points, which is lower than the passing criterion by 17 points.

Student 15: Tell her mother that Malee’s score is lower than the mean only by 7 points.

Students whose responses included arguments using, implicitly or explicitly, the ratio, the actual percentage or the proportion of elements having a particular characteristic within the distribution of outcomes (e.g., the percentage of students who passed and/or failed the test), fell into the *proportional reasoning* category. All 26 students (100%) gave answers falling into this category. The following two sub-categories were identified under this category: *implicit proportional reasoning* (i.e., responses including arguments suggesting an implicit consideration of sample proportions, population proportions, or percentages); and *explicit proportional reasoning* (i.e., responses including arguments explicitly mentioning the ratio, the actual percentage or the proportion of elements having a particular characteristic within the distribution of outcomes).

In this study, a total of 11 students (42.3%) were categorized as implicit proportional reasoners. The next quote illustrates the category “Implicit proportional reasoning.”

Student 1: Tell mom that Malee’s score is more than the median, and there were only 16 students who got more than 33 points and 23 students who got less than 33 points. Therefore, her score is somehow satisfying under these criteria.

In this study, a total of 15 students (57.7%) were categorized as explicit proportional reasoners. The next quote illustrates the category “Explicit proportional reasoning.”

Student 3: From the box-plot diagram, it was found that Malee’s score (33 points) is higher than ... the scores of 50% of the total students but not reach the score of the 75%.

Students’ responses coded as *distributional reasoning* included arguments integrating two or more key features of the distribution of scores, such as centers (e.g., mean, modes, proportions), shape (e.g., skewness), spread (e.g., range, standard deviation) and outliers. A total of 4 students (15.4%) fell into this category. The next quotes illustrate the category “Distributional reasoning.”

Student 6: From interpreting the standard deviation, Malee’s score lies to the left of the mean, where most of students’ scores are. However, Malee’s score is in the range between  $Q_2$  and  $Q_3$ , which is higher than 50% of students who got similar scores.

Student 12: Most of the students’ scores skew to the left of the median.

### **Participants’ ways of modelling variability**

Eleven ways of modelling variability by the students were identified (see Table 2). Students were allowed to represent the data in more than one way, resulting in a total percentage of more than 100%.

Model code	Type of model	Model description	Frequency (%)
$M_1$	Visual	Sorted data array	13 (50)
$M_2$	Visual	Stem-and-leaf plot	7 (26.9)
$M_3$	Visual	Boxplot*	7 (26.9)
$M_4$	Visual	Pie chart	1 (3.8)
$M_5$	Visual	Bar graph	1 (3.8)
$M_6$	Visual	Visually estimated skewness	2 (7.7)
$M_7$	Mathematical	Mean	4 (15.4)
$M_8$	Mathematical	Median	8 (30.8)
$M_9$	Mathematical	Mode	8 (30.8)
$M_{10}$	Mathematical	Standard deviation	2 (7.7)
$M_{11}$	Mathematical	Frequency distribution	13 (50)

Note. \* Students who drew boxplots calculated the three quartiles of the distribution of scores. Quartiles are also mathematical models.

Table 2: Summary of the different types of models developed by the participants in this study

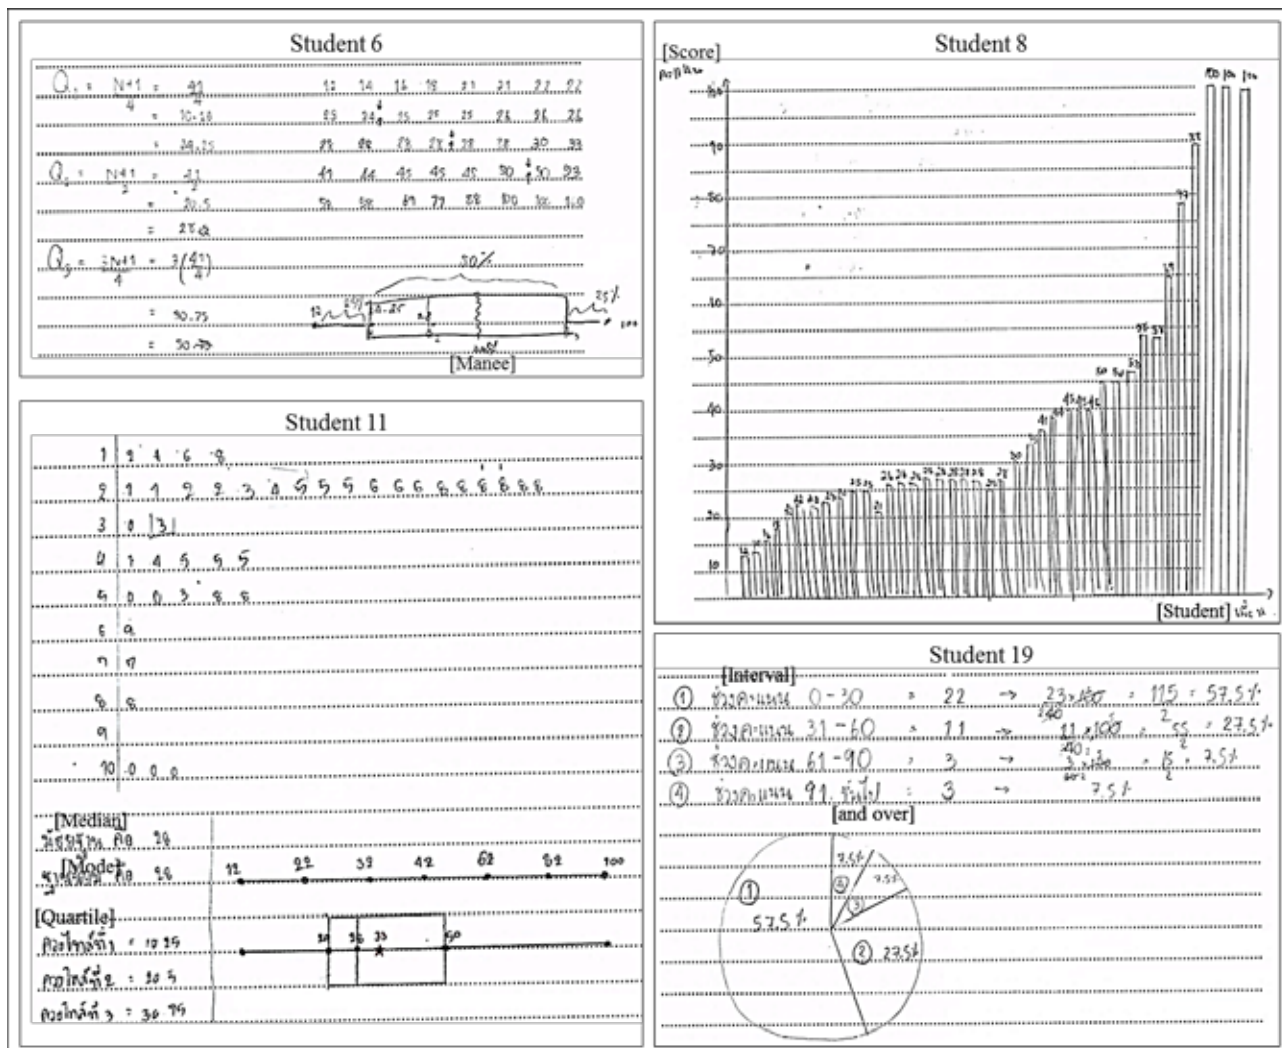

Figure 2: Examples of different types of models developed by the participants in this study

On average, two to three models were provided per student, being the mode 2 models (9 students, 34.6%), and the number of models developed by participants ranged from 1 to 5. As can be seen in Table 2, sorted data arrays (13 students, 50%) and frequency distributions (13 students, 50%) were the models most used by students when answering the given task. In relation to students' reasoning about variability in this task, it is worth noting that only 1 student out of the 14 who provided evidence of either value-relation reasoning or magnitude-comparative reasoning drew and used a boxplot to support her argument. This comes as no surprise, given that value-relation reasoning and magnitude-comparative reasoning focus on attending to individual or groups of cases, rather than aggregate features of data sets as a whole (Watson, 2018). On the contrary, 6 out of 7 of the students who drew a boxplot in this task gave reasons explicitly using proportions (i.e., explicit proportional or distributional reasons). Moreover, all the participants engaged in some total ordering of all sample elements, either via a sorted data array, a frequency distribution, or a stem-and-leaf plot.

Some of the models developed by participants in this study are shown in Figure 2. Some misunderstandings in the construction and use of certain models were identified during the data analysis (e.g., the bar graph in Figure 2). This issue will be addressed in a future publication.

## Conclusions

It can be concluded that participants relied more on value-relation or magnitude-comparative reasons in their arguments, in comparison to distributional ones. However, all participants used, implicitly or explicitly, proportional reasoning, which was evident from the use of proportions or relative frequencies in all their responses. This fact suggests that participants are somehow good proportional reasoners in general, but still weak distributional ones. The source of this difficulty could be rooted on the fact that, in Thailand, students learn about stem-and-leaf plots, boxplots and quartiles in Grade 12 (participants' current grade), and they may need more time and/or experience to master those ideas.

It can be also concluded that asking students to provide persuasive arguments based on data, in the context of a socially open-ended problem, will give them opportunities to, among other things, (1) make meaningful use of distribution features such as center, proportions and spread; (2) structure variation and coordinate variability and chance by engaging actively in modeling challenges; (3) develop an aggregate view of data; (4) engage in data-driven argumentation by enacting the practice of argumentation as advocacy; (5) actively engage in the decision-making process, in order to choose and generate models able to concisely describe a body of data and capture the essential characteristics of a real-life phenomenon; and (6) develop students' awareness of variability.

Finally, we can conclude that socially open-ended problems with the characteristics described here seem to be a way to help teachers achieve the aims of the mathematics curriculum about statistics education. Moreover, the results reported here provide teachers and researchers with insight into students' ways of reasoning about and modeling variability, which can be used to improve teaching practice, design better curriculum materials, and uncover misconceptions about statistical ideas.

## Prospective teachers' interdisciplinary learning scenario to promote students' statistical reasoning

Ana Henriques<sup>1</sup>, Hélia Oliveira<sup>1</sup> and Mónica Baptista<sup>1</sup>

<sup>1</sup>Instituto de Educação, Universidade de Lisboa, Portugal

achenriques@ie.ulisboa.pt; hmoliveira@ie.ulisboa.pt; mbaptista@ie.ulisboa.pt

*Keywords: Learning Scenario, STEM, Representations, Statistical reasoning, pre-service teacher education.*

The development of students' ability to reason about data and to use data effectively and critically for prediction and decision-making is a priority in statistics education (Franklin et al., 2007), allowing to prepare 21<sup>st</sup> century students to succeed in today's society (Watson & Fitzallen, 2010). Statistical reasoning has a clear dependence on adequate data representation to support decision-making and argumentation, a process that has proved to be problematic for the students (Chick, 2004). A successful data analysis depends on students' knowledge on what types of representation are useful and on a set of transnumeration actions that facilitate to transform data in ways that lead to such representations or to alter them, making the representations convincing in terms of the evidence they provide from data claims (Chick, 2004; Wild & Pfannkuch, 1999). Such actions, as proposed by Chick (2004), are: Sorting; Grouping; Calculation of frequency, proportion or statistical measures; and Graphing. A pedagogical possibility to foster students' ability to use the representations fluently and effectively is the use of learning scenarios (Clark, 2009) that promote the integration of science and mathematics with technology. STEM (Science, Technology, Engineering and Mathematics) integration is widely recognized as an important foundation for statistical reasoning, given its potential to deepen students' understanding of the purpose and utility of data in making meaning of the real-world, an aspect suggested in curriculum documents but that has been neglected in statistics education (Fitzallen et al., 2018). Therefore, it is essential to engage prospective teachers (PTs) in activities that provide opportunities to improve their confidence and effectiveness on developing STEM integration activities, in school (Ní Ríordáin, Johnston, & Walshe, 2016). However, research is still needed to document in detail how PTs plan and implement learning scenarios in context of STEM to teach statistics topics and how students benefit from this experience (Huey et al., 2018).

This study is based on a teacher education experience involving 10 PTs of Physics and Chemistry and of Mathematics. The PTs, organized in mixed small groups and in collaboration with the teacher educators (the authors), developed an interdisciplinary learning scenario that includes a sequence of three lessons for the 8<sup>th</sup> grade, around an inquiry task that integrates Statistics and Physics and requires decision making and argumentation based on data. In this poster, we focus on students' activity regarding Statistics, in this context, aiming to analyse their transnumeration actions when using the software *TinkerPlots*<sup>TM</sup> (Konold & Miller, 2005), for data handling, in the exploration of the inquiry task.

The study follows a qualitative and interpretative methodology. Data collection methods include the students' written work on the inquiry task, the records of their work in *TinkerPlots* and the video

records of the learning scenario lessons. The results show that students made appropriate choices of graphical representations and intentionally used transnumeration actions, taking advantage of the potential of the *TinkerPlots* to support the interpretation of data and to obtain evidence for their statements. The work carried out around the representations allowed to guide the students to understand how to organize the data and analyze them in order to answer the questions or draw conclusions. These results evidence the benefits of the learning scenario to foster students' ability to reason about data. Nevertheless, it seems that students still need more opportunities to learn how to articulate different representations, either static or dynamically, an issue that demands greater attention from the PTs in the planning and enactment of the learning scenario.

Study supported by national funds through FCT, Project "Technology Enhanced Learning at Future Teacher Education Lab" (PTDC/MHC-CED/0588/2014).

# The development of a domain map in probability for teacher education

Judith Huget

Bielefeld University, Faculty of Mathematics, IDM, Germany; [jhuget@math.uni-bielefeld.de](mailto:jhuget@math.uni-bielefeld.de)

*The importance of probability increased in German teacher education in the last decades. However, research about the professional knowledge of (prospective) teachers focused on other content such as number theory and functions rather than probability. The project “The development of professional knowledge of prospective teachers in probability” aims at developing a test in order to measure teacher knowledge in probability. In order to measure content knowledge and pedagogical knowledge in this domain, one has to identify categories, concepts and ideas and connections between. This paper shows the development of a domain map, which indicates categories, concepts and ideas. The theoretical framework, the procedure of developing and an outlook is given.*

*Keywords: Mathematics education, mathematics teachers, teacher competencies, teacher competency test, probability.*

## Introduction

In the state North Rhine-Westphalia in Germany, stochastics was not obligatory for the general qualification for university entrance until recently. Teachers could decide to exclude topics for the finals. Now stochastics is mandatory. The focus of studies about professional teacher knowledge was not on probability, which is part of stochastics. The main aim of this project is to develop a test to measure the development of content knowledge and pedagogical content knowledge of prospective teachers in probability. While developing items, one has to identify necessary categories in probability to develop items to measure content knowledge in that area. This paper identifies structures and categories by developing a domain map, which shows the content of probability. Those maps, which Hill and Bell developed for their study as well (2007), help distinguish categories in probability and draw important connections between categories in order to develop items. In order to develop this domain map, educational standards and curriculums were analyzed and an expert study was conducted.

The paper is organized as follows. In the first chapter, the theoretical frame will be presented. Afterwards, the two steps of the domain map development will be demonstrated. In the outlook, the domain map is integrated into the test design and the timetable of the test is presented.

## Theoretical Framework

### Models of Teacher Knowledge and Competencies

In this chapter, models of teacher knowledge and teacher competency tests are introduced. Shulman's categories of teacher knowledge, the studies COACTIV and TEDS-M are presented to determine the theoretical framework of this paper.

Initially, Lee S. Shulman (1986a, 1986b; 1987) developed categories of teacher knowledge: content knowledge, general pedagogical knowledge, curriculum knowledge, pedagogical content knowledge,

knowledge of learners and their characteristics, knowledge of educational context and knowledge of educational ends. Several other researchers adopted Shulman's model and adapted it (e.g. Bromme, 1992, Hill et al., 2008 and Schumacher, 2017).

In the study COACTIV, conducted in 2003/2004 by Stefan Krauss et al. (2008), which is about professional competence of teachers, cognitively activating instruction and development of students' mathematical literacy, Shulman's category "content knowledge" was specified. Krauss et al. (2008, p. 876) declared content knowledge as "a teacher's understanding of structure" and pointed out possible notions of "content knowledge", while using (3):

1. The everyday mathematical knowledge that all adults should have.
2. The school-level mathematical knowledge that good students have.
3. Mathematical knowledge as a deep understanding of the contents of secondary school mathematics curriculum.
4. The university-level mathematical knowledge that does not overlap with the content of the school curriculum (e.g., Galois theory or functional analysis).

Another study is the first cross-national large-scale study, conducted by Sigrid Blömeke, Gabriele Kaise and Ralf Lehmann. The Teacher Education and Development Study in Mathematics (TEDS-M) had the main aim "to understand how national policies and institutional practices influence the outcomes of mathematics teacher education" (Döhrmann, Kaiser, & Blömeke, 2012, p. 325). The definition of teacher knowledge was also based on Shuman's definition. Pedagogical content knowledge was differentiated into (1) curricular knowledge and knowledge of planning for mathematics teaching and learning and (2) knowledge about enacting mathematics for teaching and learning. Content knowledge was differentiated into three cognitive elements, namely, knowing, applying and reasoning and was tested in four content domains, which were number theory, geometry, algebra and data (Döhrmann, Kaiser, & Blömeke, 2010).

Probability as a content domain was underrepresented in both COACTIV and TEDS-M, but the distinction of content knowledge of COACTIV and the definition of pedagogical content knowledge of TEDS-M is based on this project's definitions. However the definitions of content knowledge of COACTIV and pedagogical content knowledge of TEDS-M will be used as a working definition.

### **Domain map in probability for teacher education**

While content domains like "number" was differentiated in eight categories at TEDS-M, data had only three categories, which included data organization and representation, data reading and interpretation and chance (Döhrmann et al., 2010). Only chance can be allocated to probability. In order to grasp possible developments in professional knowledge in this mathematical field, one has to distinguish it into more categories.

### **Methodology**

The research question is which categories of (future) teacher knowledge the research area of probability can be distinguished. In order to answer this question a domain map was developed.

This distinction can be divided in two steps. First, one can raise the question what students in secondary level should learn, therefore what teachers also have to know. This can be assigned to the second notion of specification of content knowledge, which is the school-level mathematical knowledge that good students have. For carving out details, what students should learn, one will analyze educational standards and curriculums. For this paper, the German educational standards and the curriculum of the state NRW were being taken in to consideration. The statements being made to probability was first collected, analyzed and linked, so a first draft of a domain map can be presented.

The second step is to determine content knowledge in probability on the third notion, which is mathematical knowledge as a deep understanding of the contents of secondary school mathematics curriculum. On this notion, student knowledge is not adequate. In this step, content requirements for teacher education get augmented in the same way as in step 1.

After that, an expert study in a small frame was conducted. Mathematicians and Mathematics educators were being questioned about possible missing or redundant categories. In this study were three Mathematicians and ten Mathematics educators.

### **Step 1: Analysis of the German educational standards and curriculum of the state NRW in probability**

The German educational standard in probability for students in secondary level was resolved by the Permanent Conference of the Ministers of Education and Cultural Affairs of the States in the Federal Republic of Germany. The key content “data and chance” states the following about probability (KMK, 2003, p. 12):

#### Students

- reflect and evaluate arguments, which are based on a data analysis
- describe appearance of randomness in everyday situations
- calculate probability at random experiments

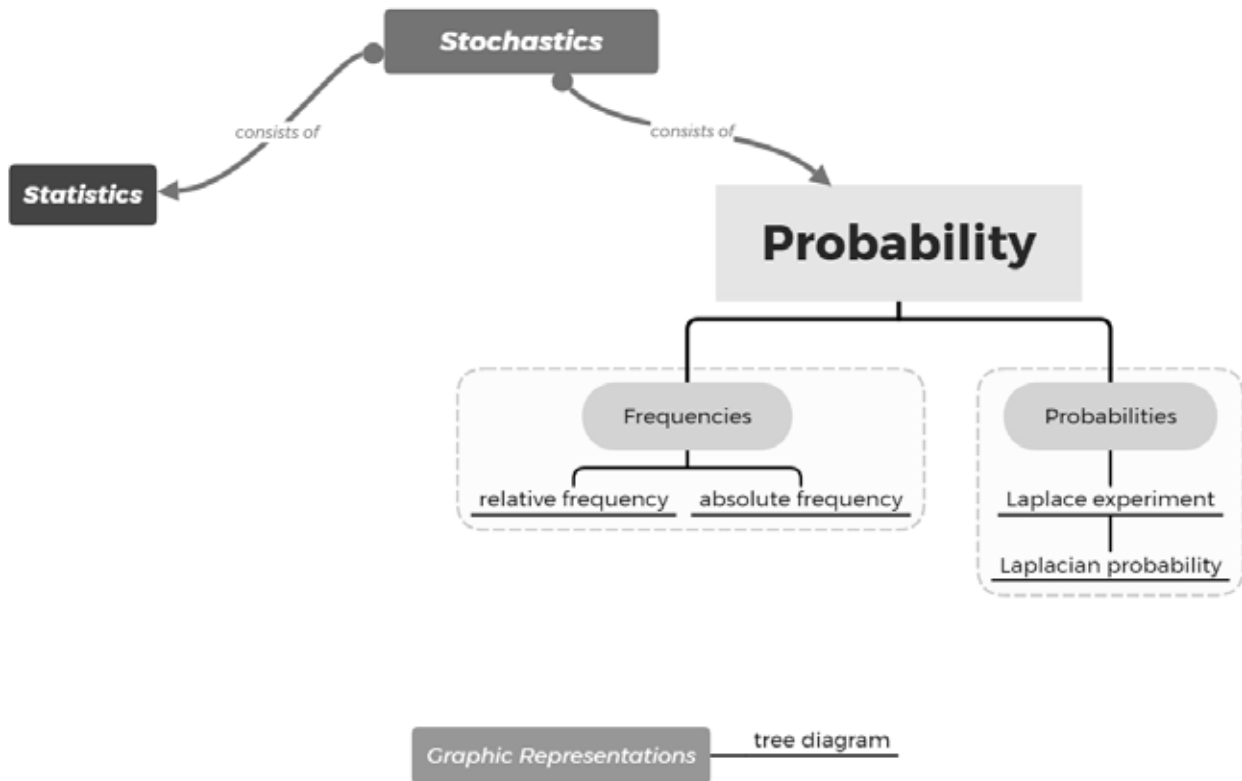

While the first indent is still clearly located in statistics, it does have some relevance to probability. The second indent establishes the concept of randomness [...] teachers should know about. In the third one, random experiments and probability are not further specified.

In the following, one curriculum, namely the one from North Rhine-Westphalia, will be analyzed to find out about notion 2 of probability. This analysis is one example for analyzing other curriculums to get a good idea of requirements for teachers in probability.

In the curriculum of the state NRW, the Ministry of Education and Training (2014, p. 16) stated more specified information about what students should know at the end of the secondary level:

- They [the students] calculate relative frequencies, mean values (arithmetic mean, median) and measures of variation (range, quartile) and interpret those.
- They [the students] calculate probabilities by using the Laplacian rules, tree diagrams and their rules, use frequencies to estimate probabilities and probabilities to predict frequencies.

Those two indents give a first idea of structuring the domain “probability” by differentiating it into the categories frequencies (relative and absolute), (Laplace) probabilities, graphic representation (tree diagram), as to be seen in Figure 1.

**Figure 1: Domain map after step 1**

Stochastics can be distinguished into Statistics and Probability. Probability has the category “Frequencies”, which contains relative frequency and absolute frequency, the category “Probabilities”, which contains Laplace experiment and Laplacian probability and the category “Graphic Representations”, which includes tree diagrams.

After completing step 1, one can use Figure 1 and differentiate the categories further and adapt it to achieve a domain map for notion (3).

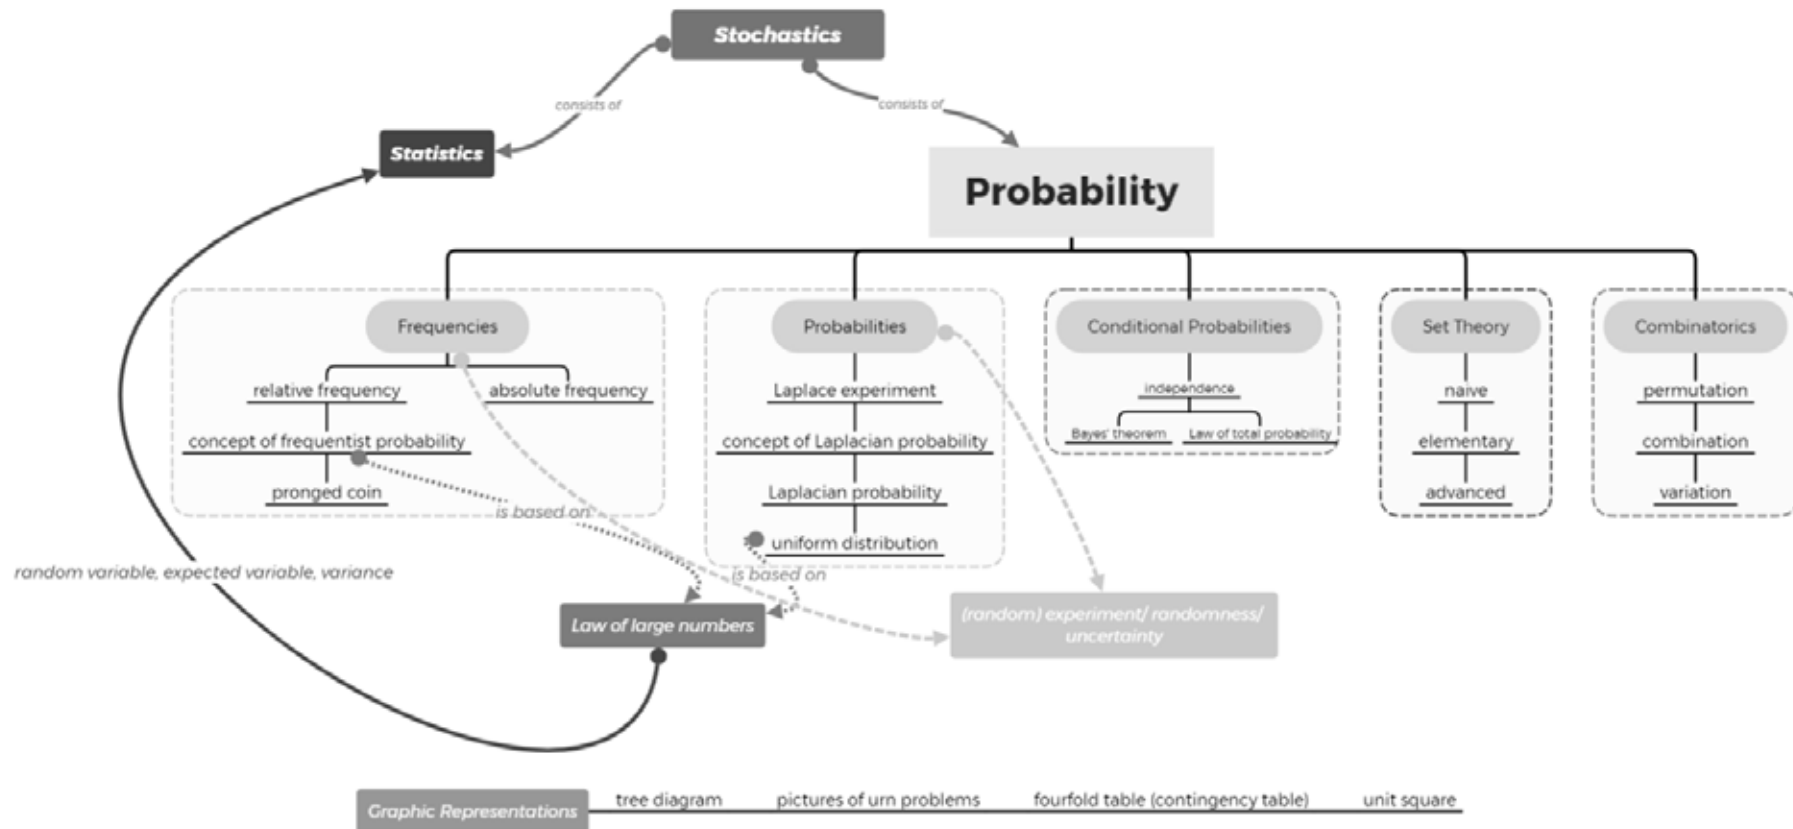

Figure 2: Domain map after step 2

## **Step 2: Obtaining a domain map for teacher knowledge as the deep understanding of the contents in probability**

In order to obtain a domain map for a teacher knowledge as deep understanding of the contents in probability, one augments Figure 1 by analyzing the content requirements for teacher education (KMK, 2008). After that, Mathematicians and Mathematics Educators from the Mathematics department at Bielefeld University were invited to critically analyze the categories. Finally, literature such as Arbeitskreis Stochastik in der Gesellschaft für Didaktik der Mathematik e.V. (2018), Harten and Steinbring (1984), Krüger, Sill, and Sikora (2015), Kütting and Sauer (2011), Tietze, Klika, and Wolpers (2002) and Wolpers and Götz (2002) was taken into account. The results were the following (see Figure 2).

The category “Frequencies” was extended to the concept of frequentist probability and, as an example, a pronged coin, while “Probabilities” has the extension of the concept of Laplacian probability and uniform distribution. Both concepts are based on the law of large numbers, which is indicated by the dotted arrows. In order to obtain a deep understanding of both categories, one needs a profound concept of (random) experiments, randomness and uncertainty. Therefore, those are important connections between frequencies and probabilities.

The law of large number is linked to statistics through the concept of random variables, mathematical expectation and variance, because many concepts of statistics are modeled via random variables. This is indicated by a solid line in Figure 2.

The category “Graphic Representations” was extended by pictures of urn problems, fourfold table and unit squares to cover the main graphic representations used in probability. To achieve a deep understanding of tree diagrams, one should know about “conditional probabilities”, because tree diagrams are based on the law of total probability and Bayes’ theorem. The category “Graphic Representations” stands on its own, because as representations it isn’t any traditional content of probability. However, graphic representations can help understand concepts of probability.

The category “Combinatorics”, which is typically categorized as algebra, was added, because of the importance for random experiments. Teachers should know about permutations, combinations and variations.

The category “Set Theory” was added, because one needs naïve set theory to grasp the idea of probability and complementary probability. Set theory on an elementary level is in use for combinatorics. Advanced set theory is mandatory for conditional probabilities.

This domain map makes no claim to be complete. However, it is the foundation to work on developing items to test content knowledge regarding these topics.

## **Outlook**

The study “The development of professional knowledge of prospective teachers in probability” is focusing on content knowledge and pedagogical content knowledge of prospective teachers. Prospective teachers for secondary school usually take their probability courses in one semester. They will participate in a pre- and post-test, so the development of knowledge in probability is visible. After a certain time, they will also participate at a follow-up-test to measure effectiveness of their

probability education. They will also answer questions about emotions toward probability, demographics and self-efficacy.

The research questions of the study are the following:

- How is the development of professional knowledge of prospective teachers in probability?
- How do emotions influence the development?
- How is the self-efficacy changing during those classes?
- How effective is the university education in probability?

One important preparation for the pre- and post-test was the development of this domain map. Educational standards, curriculums and requirements for teacher education were analyzed and Mathematicians as well as Mathematics educators were being questioned in an expert study. One now has an overview of current research on probability knowledge of (prospective) teachers and is being able to develop items for the study mentioned above. One limitation is that the domain map was only analyzed by German standards. The expansion to an international level is planned. Another limitation is the aspect of the educational standards and teacher requirements. They already are developed and assessed by Mathematics Educators on basis of empirical results, but they are not empirical results themselves. However it is a good estimation for what prospective teachers should learn in probability.

# Testing the negative recency effect among teacher students trying to generate random sequences

Olav Gravir Imenes

Oslo Metropolitan University, Norway; [ogim@oslomet.no](mailto:ogim@oslomet.no)

*Students of a teacher training program (N=124) were asked to generate, unaided, a binary sequence of 40 symbols appearing to be as random as possible. It was found that the average probability of alternation,  $P(A)$ , was 0.61, which agrees with previous experiments described in the literature, and that the students tend to underestimate the occurrence of runs with four or more equal symbols. When comparing to random sequences I argue that only asking for sequences of length 40 will overestimate  $P(A)$ .*

*Keywords: Negative recency effect, randomness, probabilistic reasoning.*

## Introduction

One of the goals of education in the subject of probability is to give students a better understanding of what constitutes random events and how to recognise random events. A democracy needs citizens that can understand and evaluate quantitative information and statistical analyses (Utdanningsdirektoratet, 2012). Media sometimes reports clusters, for example the occurrence of many cancer cases in small communities, without acknowledging that such clusters may arise as a result of randomness. Knowledge of what to expect of random events is necessary in order to know how to process such information. However, it is difficult to get a good grasp of probability, and especially the occurrence of clusters. One type of cluster occurs in binary sequences. A binary sequence is a sequence that consists of two symbols, for example the sequence generated by tossing a coin multiple times and noting whether the outcome was head or tail, or throwing a die and noting whether it displays an even or odd number. The former could look like THHHHTTHTT, while the latter could look like 0111100100. A cluster in a binary sequence is a long run of the same symbol, for example four heads or four odd numbers in a row. Research (Bryant & Nunes, 2012; Chiesi & Primi, 2009; Falk & Konold, 1997; Williams & Griffiths, 2013) shows that people overestimate the number of changes in order for a binary sequence to be random and underestimate the average length of runs, i.e., the number of times a symbol is repeated consecutively.

In Norwegian schools in the last 20 years there has been a stronger emphasis on probability than previously, especially with the introduction of curriculum reform in 1994 for high school, R94 (Kirke, utdannings- og forskningsdepartementet, 1999), and in the curriculum reform in 2006 for both primary and secondary school, LK06 (Kunnskapsdepartementet, 2013). For example, the curriculum for the first year of high school demands that the student should be able to produce examples and simulations of random experiments (Kunnskapsdepartementet, 2013, p. 11).

One might ask what the stronger emphasis on probability means to students' understanding of clusters. If, successively, an even number has been thrown four times with a fair die, and students are asked if there is still a 50% chance to throw an even number in the next throw, most will immediately answer yes. However, when asked to construct sequences, they may tend to

underestimate such probabilities, i.e., seemingly assigning a less than 50% chance of getting the same result as in the previous throw. This paper will focus on Norwegian teacher students' understanding of what constitutes a random binary sequence. In order to measure the randomness of binary sequences, Falk and Konold (1997) presents a framework for analysing binary sequences mathematically, using among other indicators a probability of alternation,  $P(A)$ . I will be using parts of this framework.

This paper sets out to explore the following question: To what extent are Norwegian teacher students able to understand the probability of forming of clusters in a binary sequence? The guesses will be measured by the calculated  $P(A)$ , and by testing whether or not the students' guesses for the number of runs of given lengths differ significantly from that of a fair die thrown.

## Review of the literature

Children's and adults' understanding of what constitutes a random sequence tends to show some common misconceptions. One such misconception is the negative recency bias (Bryant & Nunes, 2012, p. 10). This is the assumption that after a long sequence of the same result, e.g., six heads in row when tossing a coin, a tail is more likely in the next toss. The counterpart of this misconception is the positive recency bias (Bryant & Nunes, 2012, p. 10), in which people estimate that a certain result is more likely to be the next outcome because it has occurred frequently in the past. Positive recency bias occurs in for example estimating scoring in baseball (Gilovich, Vallone, & Tversky, 1985). Many studies have been carried out investigating the negative recency effect. For surveys of such investigations, see for example Batanero and Sanchez (2005), Bryant and Nunes (2012), Chiesi and Primi (2009) and Falk and Konold (1997).

Some of the studies carried out ask the participant to tell which of two or more sequences or patterns are random and which are not (Batanero & Serrano, 1999; Falk & Konold, 1997; Kahneman & Tversky, 1972) or which result is more likely to come next (Chiesi & Primi, 2009; Fischbein & Schnarch, 1997), and such studies are examples of judgement tasks. Others ask the participants to generate random sequences (Bakan, 1960; Towse & McLachlan, 1999), and are production tasks. A variation is studied by Rapoport and Budescu (1992), where the participants generated random numbers as part of a game. Bar-Hillel and Wagenaar (1991) argue that judgement tasks are a purer way of studying the perception of randomness. However, the basic biases were discovered by production tasks, since these tasks were the ones in the early research. Another problem with judgement tasks is that when a researcher asks whether or not a given sequence is random, he may not himself know the answer. For example, Green (1982, p. 157) provides an example of two binary sequences of length 150 and 153 respectively and asks the subject to determine which sequence is made up. The one he would classify as not made up has a  $P(A)$  as low as 0.44 in addition to having one run of length 9, which is not expected for such a short sequence. At least when assigning production tasks, the researcher does not need to say anything wrong. In addition, when assigned production tasks, the students cannot guess among the alternatives, thus taking a more active role.

Falk and Konold (1997) present a framework for analysing binary sequences with respect to randomness. For every binary sequence a number called probability of alternation,  $P(A)$ , may be

calculated. It is given by  $P(A) = \frac{r-1}{n-1}$ , where  $r$  is the number of runs, and  $n$  is the length of the sequence (Falk & Konold, 1997). In an infinitely long, truly random binary sequence, the expected  $P(A)$  is 0.5. The  $P(A)$  measure first order dependencies. Another measure is the second-order entropy ( $EN$ ). This is based on the relative frequency of all ordered pairs, and is a measure of the amount of new information provided by the second symbol of the pair (Falk & Konold, 1997). The second order entropy is maximal ( $EN = 1$ ) when all the four pairs, 00, 01, 10, 11, are equally probable. It is minimal ( $EN = 0$ ) when  $P(A) = 1$ . Yet another measure is the complexity of the sequence, and can be defined as the “bit length of the shortest computer program that can reproduce the sequence” (Falk & Konold, 1997, p. 306). Another method Falk and Konold describes, due to Garner (1970), is to sort all sequences of a given length  $n$  into different disjoint sets based on their  $P(A)$ . The most random sequences are the ones contained in the set which consist of the maximal number of sequences. In this paper we will focus on the  $P(A)$ , and also of the number of subsets of length  $m$  with  $P(A) = 0$ , that is, the number of runs with a given length.

The typical value of  $P(A)$  for a binary sequence constructed by a person seems to be around 0.6. The nine studies referenced by Falk and Konold (1997) have  $P(A)$  ranging from 0.56 to 0.63. For nine experiments, referenced in the same paper, where participants are judging whether or not a certain sequence is random the  $P(A)$  range from 0.57 to 0.65 in eight of the experiments while one has a  $P(A)$  of between 0.7 and 0.8 (Gilovich et al., 1985). Thus, the literature seems fairly consistent regarding the extent to which people overestimate the number of runs. However, there seems to be a lack in reporting standard deviation. It is also interesting to examine to what extent people tend to underestimate the possibility of long runs, which we may call clusters. The most consistent result on binary sequences is that both in generating and perception people tend to underestimate the number of long runs, i.e., consecutively equal results (Falk & Konold, 1997, p. 302).

## Method

I had 127 students enrolled in the first-year teacher education study program providing me with data. For entry into the program the students need more than a passing grade in mathematics from high school. In Norway, the lowest grade in high school is a zero, while 6 is the best obtainable grade. The requirement for entry to the teacher education program is a 4, while 2 is the lowest passing grade. Thus, the enrolled students had a somewhat better understanding of mathematics than that required for other study programs. As they were about to start learning about probability and combinatorics, the students were asked to imagine the following task: Throw a die 40 times and mark for each throw whether you get an even or an odd number. Mark an even number with 0 and an odd with 1. The students were asked to write down as realistic a sequence as possible. Afterwards they were asked to actually throw a die 40 times, and compare the results. Thus, I had about 5000 actual die throws to compare. The students were informed that the data they provided could be used for research. All data were collected anonymously. Among the participants three students did not produce a binary sequence of at least 40 symbols, and thus they were discarded. Therefore 124 student generated guessed sequences were analysed.

In order to determine if the student made a good guess or not, the  $P(A)$  was the first indicator, and was compared with the theoretical  $P(A)$  of 0.5 and the  $P(A)$  of the actual die throws. In the latter comparison, a  $t$ -test was used since it was possible to calculate standard deviations. The second criterion was that the number of runs of each length in a guessed sequence should be approximately equal to the number of runs of that length in the thrown results. A list of the number of runs each student guessed for any given length from one to seven was made, and for each run length a  $t$ -test was carried out to compare to the corresponding list for the sequences obtained from the actual die thrown. The data was tested for normality using the Shapiro-Wilk test. A  $t$ -test ordinarily requires a normal distribution. However, the central limit theorem ensures that when the number of participants is large, it can be used even though the data does not have a normal distribution. Typically, this occurs when the number of participants is more than 30.

The tests described above were carried out using R: A language and environment for statistical computing (R Core Team, 2016).

## Results

Each student produced one sequence of 40 binary digits, representing even and odd numbers. The sequence guessed by participant number 85 is provided in Figure 1. An even number is represented by 0 while an odd number is represented by 1. Another example is given in Figure 2, the sequence of participant number 93.

**Figure 1: The guessed sequence of participant number 85**

**Figure 2: The guessed sequence of participant number 93**

In addition to guessing how such a sequence would look like, the students each threw a die 40 times, and recorded the outcome. An example of such a sequence, from participant number 88, is given in Figure 3

1000000110001000011010  
100110111110010010

**Figure 3: The actually thrown sequence of participant number 88**

The probability of alternation was calculated for each participant. The mean  $P(A)$  among the participants was 0.61 ( $SD = 0.12$ ). For the random numbers the students threw, the mean  $P(A)$  were 0.51 ( $SD = 0.08$ ), quite near the theoretical value of 0.5 for infinitely long sequences. Ten students made guesses with  $P(A) < 0.51$ . The  $P(A)$  for the estimated results were not normally distributed, the Shapiro-Wilk normality test giving  $p < .001$ , where for the random generated sequences, that is when the die was actually thrown, the  $P(A)$  was normally distributed, with the Shapiro-Wilk normality test giving  $p = .08$ . There was a significant difference between the made-up sequences compared to the actual throws ( $t(213.72) = -8.23$ ,  $p < .001$ ).

The number of runs of a given length in the estimated sequences varied. In Figure 4 the median and the quartiles of the number of runs of a given length for each student's guesses are shown in a boxplot. For each run of a given length, the corresponding result for the actual throws is shown to the right for comparison. The box labeled RLG1 shows the first and third quartile of the number of runs of length one in the guessed data as the lower and upper sides of the box. The solid line in the middle of the box is the median, and the mean is given by an asterisk. Similarly, RLG2 shows the number of runs of length two. RLT1 shows the number of runs of length one for actually thrown dice, and so on.

**Figure 4: A boxplot of the number of runs of a given length**

We note that the students tend to underestimate the number of runs of length four and five, and overestimate the number of runs of length one and two. For each run length, a  $t$ -test were carried out, and in particular it showed that for every run length except three, there was a significant difference ( $p < .002$ ) between the guessed results and the actual throws. For runs of length three, the

difference was not significant ( $t(243.31) = 1.00, p = .32$ ). With the sequence length being only 40, we cannot from this data conclude that students underestimate the numbers of run of length six or more. The reason is that with 20 expected runs, and only a  $\frac{1}{2^{(6-1)}} = \frac{1}{32}$  chance of getting a run of length six for every run started, a student trying for the most random sequence should not include runs of length six or more. Also, in Figure 4, especially note that the median of the number of runs of length five for the actual thrown dice is zero, even though the average is 0.58. However, remember that the probability to get a run of length five or more is double that of obtaining a run of exactly length five. Therefore, we should expect student guesses to include one run of length five or more, but not be surprised if none were included. We have not included runs of length longer than seven in the boxplot as no students included runs of that length in their guesses.

Among the students there are some that made better guesses than others. Among the 124 students which completed the task, 49 included at least one run of length four or more in their guessing. Of these, 14 students included a run of length five or more.

## Discussion

The average results for the probability of alternation,  $P(A)$ , when the students are guessing, is in line with the literature, being 0.61. This is significantly different from a random binary sequence. I have not found the standard deviations from the previous experiments, so no hypothesis test could be done comparing this  $P(A)$  to the  $P(A)$ 's listed by Falk and Konold (1997). However, I conclude that this number seems fairly constant across countries and time. The list compiled by Falk and Konold (1997) seems to indicate that the  $P(A)$  becomes smaller as the length of the guessed sequence increase. The result from the current experiment seems to agree with experiment where sequences of comparable length has been used. One reason for a lower  $P(A)$  when longer sequences are used may be that participants then will expect some very long runs. For sequences as short as 40, a student who knew about the correct distribution could argue, that since the median of runs of length five or higher is zero, such sequences should not be included in the guess, even though the mean is closer to one than zero, and that the expectation value for the number of runs of five or more in length is more than one. Excluding runs of length five or higher should lead to a somewhat higher  $P(A)$  than 0.5. Thus, it is not surprising that students overestimate the  $P(A)$ . However, the observed average  $P(A)$  of 0.61 is higher than should be expected even when excluding runs of length five or more.

From the results (Figure 4) we observe that the students' guesses are relatively accurate concerning runs of length five, and this is confirmed by the  $t$ -test. The problems with underestimating the number of long runs begin with runs of length four or more. Each student should have expected at least one run of length five or more, as this will happen in one of 16 cases when starting on a run, and each student would be expected to start 20 runs. The approximate number of runs is  $P(A)$  multiplied by the sequence length, in this case  $0.5 \cdot 40$ . Out of 124 students, 49 included at least one run of length four or more in their guessing. Of these, 14 students included a run of length five or more. Thus, few students think that clusters are as common as they actually are.

The probability of clusters arising in a binary sequence is comparatively easy to understand compared to the probability of clusters of for example diseases arising in a general population.

Therefore it may be a start to educate students of clusters in such a setting, when known biases can be used to give the students a better understanding of how they tend to underestimate the occurrence of clusters. It is also easier to show them their own bias when using production tasks.

## Conclusion

Teacher students do significantly underestimate the number of long runs, i.e., runs of four or more equal symbols when trying to construct binary sequences that shall appear random. They also overestimate the number of runs of length one and two significantly. They do not seem to underestimate the number of runs of length three significantly; the median guess is actually the same as for a random sequence. Also, a  $t$ -test could not determine a significant difference when it comes to sequences of length 3.

For further research it would be interesting to ask participants to generate longer sequences, for example of length 150, where 75 runs would be expected, thus at least one run of at least seven, since the probability of getting a run of seven is  $\frac{1}{2^{(7-1)}} = \frac{1}{64}$ . The current results suggest that students would grossly underestimate the occurrence of the really long runs, but a sequence length of 40 does not allow us to conclude in this case. Another interesting experiment would be to tell some of the students about what constitutes a random binary sequence and tell some of them beforehand that you are to test their sequences on the  $P(A)$  and the number of runs of each given length. Then the results of this group of students could be compared to the students not having been given such instructions. Thus one could observe what effects such instructions would have.

It would also be very interesting to ask the students to explain their thinking during the production of these sequences. This would add a qualitative dimension to the results and be useful for improving the education in order to help students understand clusters better.

The author wishes to thank Trude Sundtjønn, Siri Krogh Nordby and Grethe Kjensli for help with data collection and George Hitching for comments.

# Statistical Graphs Semiotic Complexity, Purpose and Contexts in Costa Rica Primary Education Textbooks

Maynor Jiménez-Castro<sup>1</sup>, Pedro Arteaga<sup>2</sup> and Carmen Batanero<sup>3</sup>,

<sup>1</sup>Universidad de Costa Rica, Costa Rica; maynorjc@correo.ugr.es

<sup>2</sup>Universidad de Granada, Spain; parteaga@ugr.es

<sup>3</sup>Universidad de Granada, Spain; batanero@ugr.es

*The aim of this research was analyzing the way in which statistical graphs which are introduced in the new curricular guidelines for Costa Rica primary education are introduced in the textbooks, and compare the results with previous research in other countries. We analyze the distribution of the graph complexity, purpose and context in 167 activities related to statistical graphs selected from the two most widely used textbooks series. Results suggest a non-uniform distribution in both series and suggest ways to enhance the activities proposed in the textbooks.*

*Keywords: Statistical graphs, reading level, semiotic complexity, textbooks, primary education.*

## Introduction

Statistical graphs are a main tool to represent information in the media and professional life and acquiring graphical competence is needed for citizens to manage in the information society. This need led Costa Rica to increase the relevance of statistical graphs in the primary education (M.E.P, 2012), following suggestions such as those of the GAISE project (Franklin, Kader, Mewborn, Moreno, Peck, Perry, & Scheaffer, 2007). More specifically, statistical graphs are included in the Costa Rica curriculum in Primary Education as follows:

- In second grade, bar graphs are introduced, with the main objective that the student makes a simple reading of the information and in third grade, the students are expected to construct such graphs and interpret them, using the mode, maximum and minimum.
- In the fourth grade, the student must interpret information in dot plots and it is proposed to incorporate the spreadsheet as a support tool in graphic representations.
- In the fifth grade, pie charts are included and in the sixth, the line graphs to visualize trends in data series. The graphic comparison of two or more data groups is also suggested.

These goals can only be achieved with a correct teaching of the topic and the use of adequate textbooks. There are however no available empirical studies providing evidence that Costa Rica textbooks follow these guidelines. The aim of this paper is to analyze the graphs included in Costa Rica textbooks and use this information to help teachers to organize the teaching of the topic.

## Background

### Theoretical framework

Statistical graphs are complex semiotic objects, as suggested by Bertin (1967), who remarked that interpreting a graph requires first the isolated interpretation of each element, such as the title or

scales and finally as a global interpretation of the whole graph. Moreover, Arteaga and Batanero (2011) analyzed the semiotic activity involved in the construction of graphs by prospective teachers, and suggested that different graphs may vary in semiotic complexity, according to the mathematical objects needed in this process. Specifically, the authors described four semiotic levels in statistical graphs that will be used in our analysis:

- S1. Representing isolated data. Graphs classified in this level only represent some isolated data without considering the whole set from which the data were extracted.
- S2. Representing a list of data one by one without any attempt to building a distribution. The list of data or a data set is represented in the same order in which the data are located in the list with no use of the numerical order. There is no grouping of similar values of the variable or computation of frequencies. Consequently, although in this graph the idea of variable is used, the distribution is absent. In Figure 1 we present an example.

**Figure 1: Example of graph of semiotic complexity S2 (Source: S4, p. 278)**

- S3. Representing a data distribution. These graphs include the representation of a distribution, with values and frequencies for each value; For quantitative variables, the order of the variable values in the graph axes (if used) is the ordinary numerical order (see figure 2)

**Figure 2: Example of graph of semiotic complexity S3 (Source: A5, p. 146)**

- S4. Representing several distributions on the same graph. At the highest level more than one distribution is represented on the same graph. (an example is given in Figure 3)

**Figure3: Example of graph of semiotic complexity S4 (Source: S6, p. 263)**

Following ideas by Kosslyn (1985), we also considered statistical graphs as a resource that can be used with different purposes:

- *Analysis*; when the main goal is using the graph to identify or discover many features that are hidden in the unorganized data set; for example discovering the mode or the asymmetry of the distribution.
- *Communication*; when the graph is used to transmit to another information about the data and its relationships in an efficient way.
- *Construction*; in traditional teaching, an additional purpose is providing procedures to help students learn how to build a correct graph.

Another aspect analyzed is the context of the graph, using the classification established in the PISA studies, which is described in OECD (2016), where it is suggested that the mathematical performance of an individual can be influenced by the context in which he develops his problem situation. In this sense, the context in which the collection, organization and representation of the data are circumscribed may affect the understanding of the graph. This classification contemplates the following contexts:

- *Personal context*: corresponds to situations in the scope of personal activities of the child, his family or peer group. An example of this context is presented in Figure 3, where the graph shows the activities preferred by a group of boys and girls.
- *Social context*: these contexts correspond to the problems where aspects of the social sphere are addressed, beyond the personal life of the child; for example, the neighborhood, or city. They can correspond to voting systems, public transport, government, public policies, demography, publicity, national statistics or economy. Gambling is also included in this context because it is widely used in society.
- *Labor or school context*: consist of those situations where the problem addresses aspects of the world of work: school, work, employment, production, sale, etc.
- *Scientific context*: this context is related to problems in the field of science and technology, and includes aspects such as: climate, ecology, medicine, space science, genetics, etc.

## Previous research

Research analyzing different content in textbooks is increasing today, since these books are a main didactical tool for teachers and students, and constitute an intermediate stage between the official

curricular guidelines and the teaching implemented in the classroom (Herbel, 2007). The textbook selected usually provides the main basis why the topic is taught (Shield & Dole, 2013).

Our research is based in other studies that analyzed statistical graphs in the textbooks in other countries, in particular, Díaz-Levicoy, Batanero, Arteaga and Gea (2016), who analyzed the statistical graphs included in three series of Spanish textbooks and three other Chilean series of Primary Education, and compared their results with the curricular orientations. The authors studied the type of graph, level of semiotic complexity, and reading levels implicit in the activity. They conclude the greater presence of the bar chart with little weight of other graphs included in these curricula. Regarding the level of reading, the most frequent were the intermediate ones.

## Method

For this study, the curricular orientations referring to the education of statistical graphs in Costa Rica have been analyzed, as well as the two most frequently used series of books in Costa Rica; Asociación Libros para Todos (AL) and Editorial Santillana (S), using content analysis. The sample of publishers was directed or not probabilistic, because we selected the textbooks most spread in the schools of the country (see Appendix). A total of 167 different graphs were analyzed and classified according to the following variables:

- *Semiotic complexity level*: Arteaga and Batanero (2011) observed in their study as a higher semiotic level in the graphs constructed by a sample of prospective teachers implied a higher level of reading of them by the prospective teachers. Therefore, semiotic levels are related to the reading levels of a graph, that is an important ability related to good levels of graphical competence (Wu, 2004).
- *Purpose of the graph*: Cazorla (2002) shows that statistical graphs are an instrument of both data analysis and information transmission, for all this, considering Kosslyn's ideas we classify the graphs according to their purpose.
- *Context of the graph*: Monteiro and Ainley (2007) observed how the interpretation of the graphs mobilizes knowledge and feelings that affect their understanding and how the context of the graph influences the interpretation of it, showing the importance of considering the context of the graphs when interpreting them.

Each graph was analyzed according to these three variables, Maynor, one of the authors of this paper, classified the different graphs as part of his PhD studies, and this process was supervised by the other two authors. The variables analyzed on this paper were previously used in different studies carried out by Díaz-Levicoy and published in relevant national and international journals (Díaz-Levicoy et. al, 2016, Díaz-Levicoy, Giacomone and Arteaga, 2017).

## Results

### Graph semiotic complexity

Overall the most frequent semiotic complexity level was level 3 (see Table 1) since, 67.7% of the graphs represented a distribution; 24.0% of graphs represented a data list (level 2) and only 8.4% corresponded to the highest level of semiotic complexity, representing two or more distributions in the same graph. In the AL editorial, the percentage of activities at level 2 and level 4 was 10.7%, in

contrast to 78.6% of activities classified at level 3. Similarly, at the S editorial, 62.2% of the activities were classified as level 3 and 30.6% and 7.2% as level 2 and 4, respectively.

This general data coincide with the results obtained from the semiotic analysis of the graphs in Díaz-Levicoy et al. (2016), where 58.6% of graphs analyzed corresponded to level 3. However, the second most frequent semiotic level proposed in the Spanish study was level 4 with 22.3%, while in Costa Rican textbooks it is level 2 with 24.0%. Contrary to the Spanish study's results, in the Costa Rica textbooks since the highest level of semiotic complexity (S4) represents only 8.4% of graphs.

Semiotic Complexity	AL (n=56)	S (n=111)
S2	10,7	30,6
S3	78,6	62,2
S4	10,7	7,2

**Table 1: Frequency and percentage of graphs according semiotic complexity and editorial**

Regarding the distribution of semiotic complexity by school year, in Table 2 we show the increment of semiotic complexity with school grade. In the first grade only level 2 activities were found, while in the sixth grade graphs in all the semiotic complexity levels are proposed. Moreover, in grades 2 to 5, complexity level 3 is dominant and only in the 6th grade the most common graphs are those of level 4. In Díaz-Levicoy et al. (2016) research, semiotic complexity level 4 graphs are included from grade 2, and are the most common semiotic level at fifth and sixth grades. This includes a clear difference in the way in which activities are addressed in Spanish and Costa Rican textbooks, where representations of several distributions on the same graph are scarce in Costa Rica.

Semiotic Complexity	School grade					
	1 (n=8)	2 (n=44)	3 (n=26)	4 (n=33)	5 (n=28)	6(n=28)
S2	100	29,9		15	13,6	27
S3		70,1	100	76,2	86,4	29,7
S4				8,8		43,2

**Table 2: Percentage of graphs by semiotic complexity and school grade**

### Purpose of the graph

The graph is considered according to Kosslyn (1985), as a resource that is used for analysis, communication and in traditional teaching, for purely constructive purposes. This variable has not been taken into account in previous research, so our results represent an original contribution. The activities analyzed in the textbooks tend to use the graphs for analysis purpose with 60.7% of the total graphs used for this purpose, while only 24.4% are used for communication purposes, as shown in Table 3. The constructive purpose does not seem to be so relevant to both publishers and only represents 15% of the total of activities analyzed.

When analyzing the results by grade (Table 4), we observe that the most common purpose in the first grade is communicating information and little analysis and graph construction are encouraged. In the remaining grades, the purpose of analysis predominates, although there is always an interest in graphic construction, in particular until grade 3. This variable has not been taken into account in previous investigations.

Purpose	AL (n=56)	S (n=111)
Analysis	58,7	61,8
Communication	21,7	25,9
Construction	19,6	12,4

**Table 3. Frequency and percentage of graphs according purpose and editorial**

Purpose	School grade					
	1 (n=8)	2 (n=44)	3 (n=26)	4 (n=33)	5 (n=28)	6(n=28)
Analysis	18,8	42	63,6	69,1	69,1	77
Communication	62,5	39,8	12,7	19,8	14,7	17,5
Construction	18,8	18,2	23,6	11,1	16,2	5,4

**Table 4. Percentage of graphs by purpose and school grade**

### 4.3 Contexts

The contexts of graphs are summarized in Table 5, where the most common context used in AL is primarily the school /workplace while in S both this context and personal contexts involve 33, 3%, of the activities each. Both publishers point strongly to the school / work context and to a lesser extent to scientific situations.

Context	AL (n=56)	S (n=111)
Personal	3,6	33,3
Social	28,6	18,9
School /work place	48,2	33,3
Scientific	19,6	14,4

**Table 5. Frequency and percentage of graphs according context and editorial**

The relationship of the context with school grade is shown in Table 6, where the School/work place context dominates along second to the fifth grades, mainly due to situations related to school. In the first year, personal and social contexts are more frequent, in coincidence with Mingorance's research (2014) while social and scientific contexts are more frequent in the sixth grade. Scientific context is scarce in the first school years, but increases after the fourth grade.

	School grade					
	1 (n=8)	2 (n=44)	3 (n=26)	4 (n=33)	5 (n=28)	6(n=28)
Context						
Personal	37,8	31,8	26,9	21,2	7,1	21,4
Social	37,5	18,2	34,6	21,2	7,1	28,6
School /work place	25,0	38,6	34,6	36,4	64,3	21,4
Scientific		11,4	3,8	21,2	21,4	28,6

**Table 6. Percentage of graphs by context and school grade**

## Conclusions

The two series of books analyzed, concentrate their activities at the semiotic complexity level 3 that is in the representation of a data distribution in coincidence with Díaz-Levicoy et al. (2016) results.

The results of the analysis showed that the main goal of graphs in the textbooks is analysis, followed by communication with only 18% graphs oriented only to learn how to build the graph. In our opinion more activities oriented to build a graph should be included because previous literature show the importance of graph construction as part of a good graphical competence (Wu, 2004) and because this ability is recommended in Costa Rica's curricular guidelines (M.E.P., 2012). There were also variation between the different grades with personal contexts more frequent in first grade and educational context more frequent in grades 2 to 5. In grades 1 to 3 scientific contexts hardly appear, while starting from grade 4 they constitute about a quart of all the graphs.

These results are useful for teachers who should take into account the relevance of variables as semiotic complexity, purpose and context in statistics education and select adequate activities when introducing their students to statistical graphs, because previous research show the importance of taking into account these variables in the teaching of statistical graphs (Arteaga and Batanero, 2011, Cazorla, 2002, Monteiro and Ainley, 2007, Díaz-Levicoy et al., 2016)

Textbooks are a teaching and learning resource with an important tradition within the classroom, because they provide support to teachers and students throughout the instructional process. It is therefore necessary to study how the textbooks present statistical topics as a first step to suggest possible improvement in their content and to check that they follow the curricular guidelines.

Project EDU2016-74848-P and group FQM126 (Junta de Andalucía).

## Theoretical background

In today's age of information, data is very powerful in making informed decisions. Data analytics, which is a relatively new field, refers to processes used in identifying or discovering the trends and patterns inherent in the data to get useful insights for making data driven decisions (Piccano, 2012). The Strategic Partnership for the Innovative Application of Data Analytics in Schools (SPIDAS) project (funded by Erasmus+ Programme) aims at developing students' data analytics skills at various school levels (from primary to secondary) using innovative and student-centered approach.

In the context of SPIDAS project, we define DA as a process of 'engaging creatively in exploring data, including big data, to understand our world better, to draw conclusions, to make decisions and predictions, and to critically evaluate present/future courses of actions'. Our conceptual framework for the teaching and learning of data analytics in schools consists of two components: data analytics cycle and competence areas. Data analytics cycle is drawn on PPDAC (Problem, Plan, Data, Analysis, Conclusion) statistical inquiry cycle (Wild & Pfannkuch, 1999), statistical thinking process (Wild, Utts & Horton, 2011) and informal statistical inference (Makar & Rubin, 2009, 2018). This cycle involves the following steps in solving real world problems that require data: 1) defining the problem 2) considering data 3) exploring data 4) drawing conclusions 5) making decisions and 6) evaluating courses of actions. Additionally, the data analytics cycle is complemented with various competence areas that are in line with "Framework for 21<sup>st</sup> Century Learning" (<http://www.p21.org/about-us/p21-framework>) and the Royal Society's (2016) report on the need for data analytics skills. These are statistical literacy, ICT literacy, critical thinking, creativity, communication and collaboration, ethics and social impact.

## The study

This study aims to innovate and extend best practice in the teaching of data analytics through student-centered, project-based learning, focusing on the impacts of weather. The project end-product will be the Data Analytics Toolkit, an on-line resource supporting schools across the EU to develop their data analytics projects building on our examination of the state-of-the-art and findings emerging from the pilot projects conducted in partnering schools in the UK, Spain and Turkey (<http://blogs.exeter.ac.uk/spidasatexeter>). To this end, a design study method (Cobb et al., 2003) is used for developing, testing and revising conjectures about how students develop skills and competencies related to data analytics and instructional materials to support it with the use of technology tools. The design of the pilot projects are guided by our data analytics framework. They

are implemented in nine partnering schools with 9–17 year-old students across three countries over two iterations (fall 2018 and spring 2019). One of the project themes to engage 9–12 year-old students in data analytics for solving real world problems is “How does weather affect our health and emotions?” through which we expect them to correlate weather data with other datasets, such as students’ feelings. In the first pilot study, students generated statistical questions and collected their own data from other students as well as obtained them from other sources, such as the meteorology office. Technology tools, e.g. Excel and CODAP (<https://codap.concord.org/>), were used to record, visualize and analyze their data to make decisions. Students’ work on computer and worksheets and classroom observations are analyzed to elaborate on how students interact with ill-structured real world problems to apply data analytics techniques and skills.

## Poster presentation

The poster presents an overview of the conceptual framework for the teaching and learning of data analytics in schools, objectives and context of the study, task design and preliminary findings regarding how students deal with multivariate datasets to investigate different possible relationships in solving real world problems using data analytics techniques and skills.

The Strategic Partnership for the Innovative Application of Data Analytics in Schools (SPIDAS) project is funded with support from the European Union’s Erasmus+ Programme. All views expressed are those of the authors and not of the European Commission.

# Interweaving probability games and other mathematical areas in Tamás Varga's spirit in Hungary

Anna Kiss

Eötvös Loránd University, Hungary; [annaboxx@gmail.com](mailto:annaboxx@gmail.com)

*Keywords: Complex mathematics education, probability, games.*

## Short description of the research topic

The aim of the presentation is to show how it was possible in a pilot project to interweave probability and other mathematical areas in the spirit of Tamás Varga's complex mathematics education model in Hungary.

The project was launched under the Recent Complex Mathematics Education Project<sup>1</sup>, the aim of which is to examine how Tamás Varga's relatively old, but no way outdated ideas can be implemented to match present-day challenges effectively. In this sense it is also an interesting question, I intend to address in my later research, at what point digital devices should be introduced to help discovery. As Tamás Varga proposed to use manipulatives for the earliest stages of discovery, in this presentation two games accompanied by using manipulatives are presented.

"Complex" in this sense stands for teaching different areas of mathematics at the same time, often as problems of mathematical nature arise in the real world, and thus giving students a more complex and realistic image of what mathematics and mathematical thinking is.

## Theoretical framework

Even though Tamás Varga introduced probability from early primary school (Varga, 1972) in his curriculum as early as in the 1960s (Varga, 1969), in Hungary, similarly to many other countries (Serradó, Azcárate, & Cardenoso, 2006) the majority of teachers tried to avoid or minimize teaching probability in their teaching practice (Pálfalvi, 2000). In today's curricula there are three lessons appointed in fifth grade for dealing with "possible, impossible and sure" situations. In sixth grade, no probability is included, but a chapter for statistics at the very end of the schoolyear, where in practice it is often omitted.

"Guided experience with randomness in earlier years is an important prerequisite to successful teaching of formal probability" (Steen, 1990, p. 120.). In this study guided experience was embedded into the lessons appointed for teaching fractions and arithmetic. This way, instead of linear mathematics teaching, the teacher engaged in complex mathematics teaching where consolidating other mathematical areas and guided experience with randomness became possible at the same time. This way probabilistic concepts could be introduced without need for more lessons.

<sup>1</sup> This paper was supported by the Hungarian Academy of Sciences under the Recent Complex Mathematics Education Project

This research would be worth to be continued to enable teachers to teach more mathematical areas simultaneously.

## The method

In the project, probability games were selected to be taught in a complex way in four consecutive schoolyears for fifth and sixth graders, two of which are shown in the poster. One, a modified version of the game called “pig”, where 5 and 6 are out ruled (Tsao, 2016) connects probability and fractions (Sinicrope & Mick, 1992), the other, played with two tetrahedron dice (Nilsson, 2007) connects probability and arithmetic. Student-teacher dialogues were transcribed to be analyzed in a later article to further investigate students’ knowledge construction processes (Ron, Dreyfus, & Herschkowitz, 2010).

## Research results

The aim of the pilot project was to introduce probabilistic thinking into lessons where other mathematical areas were in the focus through complex teaching. We have found that through careful planning and selection of games, it was possible to teach more in fewer lessons, and thus “engage children in considerations of chance more often and more systematically” (Lehrer, & English, 2018, p. 248).

## Pitfalls and surprises in probability: The battle against counterintuition

Signe Holm Knudtzon

University of South-Eastern Norway, Norway; [Signe.H.Knudtzon@usn.no](mailto:Signe.H.Knudtzon@usn.no)

*The teaching of probability is a great challenge, not least in the training of maths teachers. This study is built around working with teachers, concentrating on one special problem: “What is the probability of picking one red and one yellow candy from a sack containing two red and two yellow pieces of candy?” From this simple example, we explore three different ways of thinking about the teaching of probability. 1) Experimentally, 2) Combinatorically, 3) Probabilistic. Throughout, we will discuss the question: “What does a student/teacher need to do in order to involve all three approaches in her teaching?”*

*Keywords: Probability, combinatorics, exploration, representations, working with teachers*

### Introduction

In general, a teacher does not only need to know that there are several ways to approach a problem in probability, but also that there are more than one method to solve a probabilistic problem. A good teacher also needs to be open to the possibility that some students may think quite differently than the teacher thinks herself. This implies that the teacher must be able to communicate well with the students, listen to their arguments and try to understand their reasoning when they work on mathematical problems. Obviously, this requires that the teacher possesses a solid understanding of the subject she is teaching.

The counterintuitive nature of some probability results makes probability very challenging and difficult to teach and to learn (Koeller, Pittman & Brendefur, 2015; Knudtzon 2010). Many researchers (Afeltra, Mellone, Romano, & Tortora, 2017; Batanero, Godino & Roa, 2004; Chernoff & Zazkis 2011; Falk, Yudilevich-Assouline, & Elstein, 2012; Lecoutre, 1992) have discussed difficulties in teaching probability. Recognising the challenges associated with teaching and learning of probability, the purpose of this article is to explore the question: *How can we as teacher educators help teachers to understand not only probability, but also give them confidence in teaching probability to students?*

### Background

Bryant and Nunes (2012) provide four “cognitive demands” for understanding probability. They are:

Understanding randomness; Working out the sample space; Comparing and quantifying probabilities; Understanding correlation (or relationships between events) (Bryant & Nunes, 2012, p.12)

In this study, we discuss two of these points: “Working out the sample space”, Comparing, and quantifying probabilities. One of the problems with “Working out the sample space” is that the student gives all possibilities the same probability. For instance if you flip/toss two coins, there will be three possibilities: HH, HT and TT, and they will all have equal probability. Chernoff and Zazkis

(2011, p.18) call the set HHH, HHT, HTT and TTT a “Sample Set” and see it as a point of departure to develop the complete sample space: HHH, HHT, HTH, THH, HTT, THT, TTH and TTT.

Lecoutre (1992) also describes difficulties in calculating probabilities:

... the most frequent model used is based on the following incorrect argument: the results to compare are equiprobable because it's a matter of chance; thus random events are thought to be equiprobable “by nature”. (Lecoutre, 1992, p.557)

With respect to “Comparing and quantifying probabilities”, one may calculate theoretically or one may do an investigation to study the relative frequencies of the different outcomes. This is a central element in the Norwegian Curriculum:

The aims of the studies are to enable pupils to: - find and discuss probability by experimenting, simulating and calculating in day-to-day contexts and games. (Norwegian Curriculum for the common core subject of mathematics, 2006, p.9)

When teaching probability, teachers must know that obstacles often will occur. “Expect the Unexpected When Teaching Probability” (Koeller et al., 2015).

## The Study

The data in this study mainly come from “Probability workshops” with teachers in 2010 and 2016. Both primary teachers (age 6 – 12 years) and secondary teachers (age 13 – 15) attended the workshops. The teachers who joined the workshop in 2010 were part of a four-day summer conference for teachers. The teachers in 2016 joined a one-day mathematics workshop. The sizes of the classes were 22 and 33.

First, teachers were given a task where they were asked to write down their first guess on a piece of paper and then show how they thought about the task individually. These papers were collected afterwards. Thereafter they were asked to work in pairs and “try it out”, by picking pieces of candy twenty times and write down the results. After a discussion in pairs and in small groups, we had a whole class discussion. Different ways of collecting and presenting the data were discussed as well as different ways of finding the probability of getting one piece of candy of each colour. The data collected consist of the teachers’ written responses and my field notes. Field notes from the smartboard gave the numbers in Table 2.

## The Candy Problem

The problem, as presented here, is from a textbook for 7th grade in elementary school. (Figure 1.)

“Hege has two red and two yellow pieces of candy in a small bag. Mia picks two pieces of candy (without looking).

What is the probability that Mia gets one red and one yellow piece of candy?”

**Figure 1: Two red and two yellow pieces of candy**

In the workshops for the teachers, we asked them to answer this question: “What is the probability that Mia gets one red and one yellow piece of candy when she picks two pieces from a bag with two red and two yellow pieces of candy” Guess, write down and try to explain your thoughts.

## Results

### Guessing

The first group of answers is from a workshop in 2010 and is discussed in Knudtzon (2010). Here are some of the written answers:

- 1) RR, YY, RY give  $\frac{1}{3}$  probability
- 2) The probability to pick a red piece first is 0.5, but then you have only three pieces left ...
- 3) red-red, red – yellow, 2 of 4  $\frac{2}{4} = \frac{1}{2}$   
yellow – yellow, yellow – red
- 4) the probability to first pick a yellow and then a red one is  $\frac{1}{2} \times \frac{2}{3} = \frac{2}{6} = \frac{1}{3}$   
same with red – yellow

5)  $\frac{1}{4} + \frac{1}{4} = \frac{2}{4} = \frac{1}{2} = 50\%$

- 6)  $y_1y_2$     $y_1r_1$     $y_1r_2$   
 $y_2y_1$     $y_2r_1$     $y_2r_2$     $\frac{8}{12} = \frac{2}{3}$   
 $r_1y_1$     $r_1y_2$     $r_1r_2$   
 $r_2y_1$     $r_2y_2$     $r_2r_1$

- 7) Table

	Y <sub>1</sub>	Y <sub>2</sub>	R <sub>1</sub>	R <sub>2</sub>
Y	YY	YY	RY	RY
Y	YY	YY	RY	RY
R	YR	YR	RR	RR
R	YR	YR	RR	RR

- 8) Experiment with counting:  
16 of 25 was one yellow and one red

2y	IIII
2r	IIII
yr	IIII IIII IIII I

- 9) (a drawing of the four pieces of candy and)  
YY, YR, RR?

The participants at the workshop in 2016 were given small pieces of paper (yellow post-it-stickers), and were asked to write down their guesses and possible explanation individually. The answers and some of the explanations are given in Table 1. (Including the frequency of each answer)

answer	frequency	explanation
1/12	1	$\frac{1}{4} * \frac{1}{3} = \frac{1}{12}$
1/6	4	$\frac{2}{4} * \frac{1}{3} = \frac{1}{6}$ 1 of 6
$\frac{1}{4}$	5	$\frac{1}{2} * \frac{1}{2} = \frac{1}{4}$ one of four
1/3	6	$\frac{2}{4} * \frac{2}{3} = \frac{4}{12} = \frac{1}{3}$ YY, YR, RR one of three
$\frac{1}{2}$	13	RR, RY, YR, YY $\frac{2}{4}$
$\frac{2}{3}$	2	$\frac{2}{3}$ RY $\frac{2}{4} * \frac{2}{3} = \frac{4}{12}$ YR $\frac{4}{12}$ $\frac{4}{12} + \frac{4}{12} = \frac{8}{12} = \frac{2}{3}$
Other	2	
SUM	33	

**Table 1: Quick notes on “post it” notes from the workshop in 2016**

## Experimentation

After guessing and writing down their first thoughts, the teachers were asked to try out the experiment. They were asked to work in pairs and to write down their results. The participants had received the problem on a paper. We used different bricks, lego or centicubes as candy and different boxes or black socks as bags. This question, which will be discussed later, arose: “Shall we pick one at a time or both at once?”

There were different ways of collecting the data. Some teachers had three choices: RR, RY, YY and some had two: Two of same colour or two with different colours. They made lists: some in a line: RR, RG, RG, RG, RR, GG, RG..., but many in columns. Some kept track of how many times they had tried and some counted after a while to see if they had obtained twenty pieces altogether. Some made tables and used tally marks and fences (grouping in fives).

Some used computers or IPADs. One way of writing on a PC was:

1) yellow and red                      2) red and red                      3) yellow and yellow

At the whiteboard we collected some of the results (see Table 2.):

YY	4	1	2	4	4	4	4	4	Sum 27
YR	12	16	15	8	11	14	12	14	Sum 102
RR	4	3	3	8	5	2	4	2	Sum 31

**Table 2: Results from eight groups**

One participant said after a while, “I don’t like that we get so many with one of each.” One teacher said, “It look like there are twice as many with one of each than the other two together”.

### **The question “Two at a time or one after another?”**

In problems mentioned here the question always arises if it matters whether we take two (pieces of candy) at the same time, or take one after another. Many students, teacher students and teachers as well will argue that there is a difference. (One method is to try, to experiment, to use one method twenty times (or more) and the other twenty times and see if there is a difference.)

Sometimes I try the following:

- 1) Put your hand in the bag and grab two candies without looking. Extract your hand and open your fist. Then you have either two red, two yellow or one piece of candy of each colour in your hand.
- 2) Put both your hands in the bag at the same time and take one piece of candy in each hand. Take your hands out and open them simultaneously. Will this be the same as in the first case? Yes, again you will have either two red, two yellow or one of each colour. However, you may also note that you may have one of each colour in two different ways, you may have the red piece of candy in your left hand, or you may have it in your right hand.
- 3) Put both hands in the bag at the same time and take one piece of candy in each hand. Then open one hand first, for instance your left, then open the other hand. You end up with two red, two yellow or one red piece in your left hand and one yellow in your right hand or conversely.

A moment’s contemplation will convince most students (if not all teachers) that the probability of each outcome is not affected by which of these three procedures you use. It does not matter if you use one or two hands (or any other instrument) to pick out two pieces of candy, and it does not matter if you open one hand after another, the piece of candy is in the hand regardless and it does not change colour by waiting to be looked at.

## **Analysis**

### **Investigation, experimentation**

As seen in Table 2, different groups got different answers and the fourth group picked two candies with one colour more often than two of different colours did. Results from a small investigation will always be uncertain. However, in a class with a larger number of trials the results are more reliable.

To do experimentations is a nice variation in the ordinary mathematics classroom. It is an activity that most students can join and participate in on an equal basis. However, it is not clear that they collect and take care of their data in a way that is easy to use in further work. In addition, there is need for experience for both teachers and students.

### **Combinatorics**

Asking the question: In how many ways may we combine the four pieces of candy? Figure 2 shows that we will find two ways of making groups with one colour and four different ways of making two colour groups, if we draw the pieces of candy” and the lines connecting two and two of them.

**Figure 2: Combinatorics: Finding the sample space. Take two of four**

The sample space of taking two from four has six outcomes. Four of these are one red and one yellow. The probability of picking one red and one yellow is  $4/6 = 2/3$ . The representation given by drawing the four pieces of candy in this way (two by two, not on a line) was new for many of the participants. They enjoyed it and it is possible to extend this with more pieces of candy.

### Probabilistic thinking

I will here use the term “probabilistic thinking” in a more narrow sense that we usually do. *We do not count whole numbers; we work with numbers less than one, fractions, each of them the probability of something.* It can be represented in a tree diagram, see Figure 3.

**Figure 3: Probabilistic thinking. Tree diagram**

You can get one red and one yellow piece in two ways, by getting the red piece of candy first or the yellow piece of candy first. We get a probability of  $2/3$  of picking two different colours.

In this case we can “think in probability” in a quick way, because there is an equal amount of each colour. This is represented in Figure 4. If you take one of the four pieces of candy, there will always be two of the other colour and one of the same colour left. This gives a probability of  $2/3$  of getting two different colours.

**Figure 4: Probability, quick way**

### Three approaches

We have worked with this problem in many different ways: guessing, thinking, discussing, trying it out (investigating/experimenting), using combinatorics by finding the sample space and finding a fraction of the proportion of the outcomes. We have calculated the probability, for instance by using

a tree diagram, or by using a formula. What are the advantages or disadvantages of the various approaches? Table 3 summarizes some of my experiences.

Experimental	Combinatorial	Probabilistic
Practical	Requires correct counting	Quickest way
Everybody can take part Difficult to use in situations involving conditional probability	A safe method	General, handles complex situations
Works also in situations where there is no mathematical probability		Enhances thinking and understanding
Inaccurate for small numbers, makes it difficult to separate small differences	May get confused, problems with finding all possibilities	May be difficult
Takes much time	Can take much time	

**Table 3: Advantages and disadvantages of the three approaches**

I want to emphasize the usefulness of investigation and experimentation, especially in the beginning. Everybody may join in, but it is important to write down the results in an orderly manner. Different groups may get different results, which gives good opportunities for discussions. However, the teacher needs to know all three approaches, and how it is possible to make them interact in her teaching.

### **What may the different answers involve?**

If we look at Table 1, we will see that  $\frac{1}{4}$ ,  $\frac{1}{3}$  and  $\frac{1}{2}$  are quite popular answers. How did they emerge? The fraction  $\frac{1}{4}$  may arise from working with a sample space of four: RR, RY, YY and YR thinking that RY is one of four. It can also be a result of thinking in probability:  $\frac{1}{2} * \frac{1}{2} = \frac{1}{4}$ . Here, one takes first one red piece and then one yellow (without taking into account that there are only three pieces of candy left).

The fraction  $\frac{1}{3}$  may result from thinking in sample space; and there are three different outcomes: RR, RY and YY. RY is one of them and then we get  $\frac{1}{3}$ . Another way is thinking in probability:  $\frac{2}{4} * \frac{2}{3} = \frac{4}{12} = \frac{1}{3}$ . This is the right thinking if the question was getting the first piece of candy red and the second piece yellow.

The answer  $\frac{1}{2}$  may also be the result of different ways of thinking. A sample space of four, RR, RY, YR and YY, gives  $\frac{2}{4} = \frac{1}{2}$ . Probabilistic thinking may be  $\frac{1}{2} * \frac{1}{2} = \frac{1}{4}$  for getting RY and  $\frac{1}{2} * \frac{1}{2} = \frac{1}{4}$  for getting YR and together this makes  $\frac{1}{4} + \frac{1}{4} = \frac{1}{2}$ . Some people will say  $\frac{1}{2}$  because there are equal amounts of red and yellow pieces of candy. Others will say that the pieces of candy are either the same colour or two different colours and some will just say  $\frac{1}{2}$  and will give no reason. It is interesting to discuss these different ways of thinking and how to move further on from each of them.

## Conclusion

Working with teachers, it is my experience that learning probability and discussing ways of teaching probability at the same time is a good way. We have to create situations where it is possible to come up with “wrong answers”. If we do not give room for this, the students may close up and not want to join in. To use wrong answers as a resource, is also recommended by Afeltra et al., (2017). When we study how to collect the data and how to explain them in different ways, most teachers are interested and fascinated. From being afraid of teaching probability, they get curious and excited. By obtaining more experience with different probability situations my hope is that the topic will be less counterintuitive than it was at the outset. When the learners know what to look for and how to handle the most common probability problems, their intuitions will be strengthened.

It is important to make a safe environment, and to look at “wrong answers” as not fully developed answers and as starting points for further work. We can also turn it upside down and ask, “What question may be asked to get this answer?”

# Why does statistical inference remain difficult? A textbook analysis for the phases of inference

Rüya Gökhan Koçer and Fulya Kula

University of Twente, Department of Research Methods, Measurement and Data Analysis,  
Netherlands; [r.g.kocer@utwente.nl](mailto:r.g.kocer@utwente.nl)

*Keywords: Statistical inference, content analysis, textbook analysis*

## Introduction

Inference in statistics is one of the crucial issues to be explained as it refers to the process of making probabilistic statements about the entire population under scrutiny by only looking at a small part of it. Inference has been studied among researchers and the students' difficulties in understanding the procedures of inference and reasoning the inferential ideas is widely documented (e.g. Falk and Greenbaum, 1995). The abstract nature of inference with also the underlying complex and abstract concepts such as sample, population, and sampling distribution are documented to result in student difficulties (Bakker and Gravemeijer, 2004; Garfield and Ben-Zvi, 2008). These stubborn difficulties are persistent and also similar among students and adults. In the current study we use the proposed model for the logic of construction for representing the whole idea of statistical inference in the introductory statistics course. This model not only follows the steps in line with the suggestions of the literature (e.g., Bakker and Hoffmann, 2005) but also transcends the suggestions and carries the teaching and learning of inference further.

## Methodology

In this study, we analyzed the way in which the logic of construction is explained in one prominent textbook of statistics for the undergraduate level. The book analyzed is the tenth edition of Introduction to the practice of statistics (Moore, D. S., McCabe, G. P., & Craig, B. A. (2016), Ninth Edition, Publisher: W. H. Freeman), hence assumed to be used one of the major books of introductory statistics. The textbook covers the inference mainly in one chapter (Chapter 6) which was taken as the content to be analyzed in this study. The steps of construction direction of inference are taken as default and the textbook is analyzed according to these subtended steps with the aim of understanding how the inference framework is being taught in this widely used textbook. The analysis of the content, namely the related chapter, results in a sequence of numbers in the order of appearance.

## Results

The results of the content analysis can be seen in Figure 1. The axes of the plot seen in Figure 1 represent the order of the steps of inference as appeared in the logic of construction (See Table 1). Hence if the book covers the steps in the very same way of the construction logic as presented in Table 1, this would yield 13 points on x and y-axes which are exactly on the line:  $y=x$ . Any deviation from this line is interesting to see how inference is taught in the book different than the proposed steps in the model. The numbers on the scatterplot denote the order of the corresponding step. For instance, the reader first is introduced with step 2a, then step 4a, and 5a, etc. (as expressed by the steps of the logic of construction).

It can be seen in Figure 1 that the book covers the inference in a totally different direction, the order as stated by the steps of the model is: 2a, 4a, 5a, 1, 2b, 8, 4c, 7, 4b, 3a, and 5b. As it can also be observed from the Figure 1 the steps 3b and 6 are not covered at all. So the learner respectively reads

the following concepts or ideas through the chapter: random sampling, sampling distribution, estimating sample statistic, the meaning of population in context, random sampling and sample size, the meaning of amassed probability, normality and characteristics of sampling distribution, the area under the distribution curve, sampling distribution to be a normal distribution emerged as the values estimated accumulate, each sample constituting the sampling distribution to contain the same number of observations, and the estimated sample statistic lands on the real line on which the probabilities are massed by the sampling distribution.

Figure 1: The order of steps of inference followed by the book

## Conclusion and Discussion.

It can be seen in the result section that the crucial steps are not presented in the way the model suggests. The model suggests these steps for a better understanding of the statistical inference, which is in fact a difficult topic to understand. The reader of the book, who is also the learner, is being directed to the understanding of inference with some confusions. We believe starting from the random sampling idea, then sampling distributions, focusing on one sample and talking about the population is not the most efficient way of learning or teaching inference. Moreover, some steps (3b and 6 of the model) are missed totally. It is of great importance for students to comprehend the fact that same sized samples all would distribute different than the population, not only to understand the idea of sampling distribution but also that of inference. This step (step 3b of the model) could not be seen to be taught in the book. Besides, the step (step 6 of the model) of grasping that the estimate of the sample at hand would be separated from the center of the sampling distribution by a certain distance “d” was also not covered in the book. The difference between how the order of steps in the model and in the book are covered is worth consideration.. However, the book has a totally different order of teaching this topic. This different approach of the book is important to consider. However, a limitation of the current study is the analysis of only one chapter. We suggest the further research be conducted not only inclusion of all the related chapters but also for the other widely used statistics books.

# Young children's informal statistical inference experiences through constructing a pictograph

Gamze Kurt Birel

Mersin University, Faculty of Education, Mersin, Turkey; [gamzekurt@mersin.edu.tr](mailto:gamzekurt@mersin.edu.tr)

*This study explores the informal statistical inference (ISI) experiences through the graph construction of young children regarding the pictograph as one of the conventional data displays. Within a case study approach, interviews with 7 years-old children were conducted through a module including a task. The task designed here presents a statistical context structure which focuses on the eye colors observed in a class. Through forming a pictograph, children responded the questions in order to investigate their informal inferential reasoning ability. Findings revealed that young children's graph construction experiences could be expressed as a construct of ISI. Besides, it was concluded that the integration of context with data helped their graph construction since they analyzed data within the context.*

*Keywords: Statistics education, early childhood, informal inferential reasoning, pictograph*

## Introduction

There is a common understanding that statistical concepts can be developed from the beginning of early childhood education. As well as statistics education is a relatively newer issue for most of the school mathematics program worldwide (introduced during the 1990s in the US) (Friel, Curcio and Bright, 2001), it is even more newer for early mathematics classes. However, accepting the primary and middle school level students' difficulties which they experienced with statistical concepts, statistics education is widely considered important. Suggested *practice of statistics* from the kindergarten to fourth grade level includes both descriptive and inferential statistics such as data collection, data organization, description of data, reading the data, interpretations of data displays (bar graph, pie charts, pictographs, line graphs, etc.) (Watson, 2018). Pictographs are one of data displays which young children are engaged in order to informally investigate data. However, inferential reasoning level is left mostly on the higher levels of education, and that makes the statistics education in lower grades as composed of only computations on some basic graphical representations (Makar & Rubin, 2009). However, according to Makar and Rubin (2009), there are lots of ways to introduce ISI and to develop the ISI abilities to young children as well, such as making predictions, or generalizations or providing a situation where young children can use probabilistic language.

Informal statistical inference (ISI), or informal inferential reasoning (IIR) is a relatively newer concept, that is defined as "the way in which students use their informal statistical knowledge to make arguments to support inferences about unknown populations based on observed samples" (Zieffler, Garfield, Delmas & Reading, 2008, p. 44). They outlined the IIR framework as containing the following three main components: IIR includes (1) making inferences but not using formal statistical procedures, (2) using prior knowledge (formal knowledge of descriptive statistics, but

informal knowledge making inferences about different samples, use of statistical language) and, (3) using arguments, and making claims about populations while using the evidences gathered from samples belonging to those populations (Zieffler et al., 2008, p. 45). In fact, it could be claimed that inferential reasoning embraces an understanding of graph construction. This claim was reflected in the task design suggestions for researchers in order to study informal inferential reasoning as well (Zieffler et al., 2008).

Based on the framework characterized by Zieffler et al. (2008), Makar and Rubin (2009) tried to “broaden accessibility to inferential reasoning with data” and they highlighted three key principles: (1) generalization beyond the data through making predictions, estimations, etc., (2) data usage as evidence in order to make generalizations; and (3) use of probabilistic language in order to explain the generalization drawn while being aware of the level of certainty (p. 85). Authors saw these three elements as observable abilities which comprises the informal inferential reasoning of young children.

Makar and Rubin (2009) points to the findings regarding students’ incapability of making statistical inferences while constructing graphs. The graph construction concept as a construct was addressed as a part of graph comprehension and it was stated that graph construction was less-explained issue as compared to other constructs of graph comprehension (Friel et al., 2001). The graph comprehension highlighted by Friel et al. (2001) treats the data displays as “discovery tools” rather than focusing on the calculations of the data represented in the data display (p. 132). Therefore, the current situation of statistics education cannot be claimed to do so because of it is full of simple arithmetic calculations based on descriptive statistics such as mean, median, etc. This is also valid for early childhood level of education, since most of the activities regarding statistics asks questions like: “what is the most/least .... observed?”, “what is the difference between the most and the least ... observed?”, etc. Hence, such questions degraded statistics education to basic arithmetic and trivializes the significance of *context* in which answers to such questions could be meaningful only. Focusing on the context maybe the most distinguished property of statistical reasoning rather than mathematical reasoning. Therefore, serving statistical context-structures to young children is important so as to provide them with meaningful statistical inferences while staying in the context.

There are some studies which focuses on the issue from other perspectives. For example, McPhee and Makar (2018) studied with young children in their studies in order to investigate statistical inscriptions they formed. Their approach can be evaluated as a problem solving since it begins with a problem and children were expected to make a data analysis based on inscriptions they formed at the end. They concluded that such kind of teaching approaches can be helpful for children in order to develop desired attitudes towards statistical thinking. Another study had a focus on data representations of primary level students (grade level 4) freely while using a catapult (Fitzallen, Watson, Wright & Duncan, 2018). The researchers present their study in a STEM context and hence they also offer an effective STEM activity which can be used in statistics education. Since the data representations observed during their study were diverse and mostly case-value plots, authors concluded that they couldn’t analyze the data. However, students who selected the frequency bar charts had the opportunity to see the data in an expected manner. This result strengthens the over-emphasis on bar graphs (only in categorical variable) with a focus on calculations.

Here in this study, towards the graph construction, young children were aimed to experience with ISI while focusing on what data tells about beyond the basic calculations. My aim is to present also the ISI abilities of young children so as to claim that statistics education should not be based on the calculations from the very beginning. Since much exposure of basic descriptive statistics calculations in lower grades makes statistics education to be treated in a narrowed and limited understanding, it is currently suggested that foundations of statistical reasoning and ISI can be introduced to the young learners as well (Paparistodemou & Meletiou-Mavrotheris, 2008). Therefore, this study is significant that its findings would reveal the exploration of young children's ISI experiences while constructing a pictograph and what we can learn from their experiences as researchers in order to better introduce them to ISI experiences.

An important issue which was highlighted by Makar (2018) is the statistical context-structures. They are addressed as one of the core notions which young children need to experience in their kindergarten classes. She concluded that statistical context-structures are valuable for teachers while making them pre-cautious about directing questions and emphasizing the informal statistical reasoning while leaving the formal statistical reasoning for the higher-grade levels for students. This suggestion from Makar (2018) in order to develop statistical reasoning abilities of young children is to present statistical context-structures instead of technological tools regarding their capabilities of using a dynamic software such as TinkerPlots. Hence, they can provide a learning environment which Konold and Pollatsek (2002) addressed as a new period of learning while offering an extraordinary data analysis experience for students. As Makar and Rubin (2009) pointed out that such efforts are for understanding the beyond the data, which is aimed in fact for all levels of statistics education, not only beneath the data as it is done in early and primary mathematics classes, nowadays.

With an emphasis on ISI of young children here, conventional graphs (pictographs) were selected in a pre-designed statistical context-structure. On the contrary to what is done regarding statistics education as currently, informal statistical reasoning should be addressed without moving away from the context and without making differentiations based on the grade level. Therefore, the main aim of this study is to explore these experiences of young children with ISI through graph construction in statistical context-structures.

## **Methodology**

This study uses qualitative efforts to respond its research question and analyze the data. The design and the data collection period are based on the case study approach (Yin, 2017). The unit of analysis is each participant and then this study can be named as multiple-case study design. Through the convenient sampling, there were 7 children (3 girls and 4 boys) as participants who are 7 years old in a private school. They were from two first grade classes and were chosen by their teachers, by paying attention to their talkativeness and sociability with a stranger.

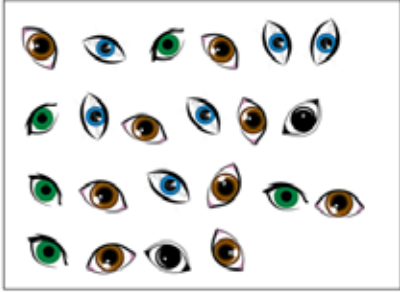

Main data collection tool is the interview. Each participant was interviewed nearly 15-20 minutes. Interview was voice-recorded and transcribed verbatim. During interview, a module designed by the researcher used in order to direct questions to the participants. These are the questions presenting a statistical context-structure which will help to explore the experiences of young children's ISI

through graph construction. Through the module each participant was also expected to form a pictograph. During their graph construction, researcher read the questions in the module. At some moments of the interview, researcher took photographs which shows the graph representations of the participants during that moment.

The module specifically presents a context of a class of a child named Ali. There are small colored movable pieces showing the eye color of each child in the class. Participant was expected to organize these onto the paper. In addition to the questions included in this module, which is shown below in Figure 1, researcher asked some further questions for example, “why did you organize in this way?”, “Is there any better way to organize them?”, etc. including the questions regarding descriptive statistics as well. The questions were generated according to the three principles which Makar and Rubin (2009) introduced and they were directed to the children without moving away from the context, which are eye colors observed in Ali’s class.

Module A – Used in the interview

Researcher reads aloud:  
Show the child the eyes of the friends in Ali's class (These are the small labels cut out of the paper):

Eye Color

1. What does this tell you? What doesn't it tell you?
2. How many friends does Ali have in his class?
3. Which eye color is seen the most in Ali's class? Which eye color is seen least in Ali's class?
4. How would you organize the data in order to understand easily the eye color of Ali's friends? (Show the place below left to the child.) Why did you do that? (according to child's response).
5. Is there any other option to organize the eye colors seen in Ali's class in order to better represent them?

**Figure 1: The module used through interview**

## Findings

The aim of this study is to explore young children’s ISI during graph construction. All of the participants completed the module while keeping the context in mind. As a prior finding, it was observed that use of statistical context-structures in early childhood level of education helps children to think between the lines of context. Then, researcher observed the principles of ISI framed by Makar and Rubin (2009) from children’s module experiences.

All of the seven children correctly gave responses regarding descriptive statistics namely the frequency or the sample size, through the questions related with the most or least seen eye color in Ali’s class, and the number of people in the class. This also strengthens the fact that their familiarity with such kind of frequency-based activities.

Regarding context, there were lots of talk about it. At the beginning of graph construction, participants asked to me how many eyes s/he should use for one person in Ali's class. I directed the question "does a person have different eye colors or not?" and they decided to use one piece of eye label for each person. Real eye colors were also discussed. For example, 2 girls asked to me why I didn't prepare hazel or honey-colored eye labels. They expected to see different blue eye labels. But they were the same since I prepared blue colored eye label in order to represent all real blue eye colors. This means that they were aware that blue eye color can be different from one person to another, in terms of color tone. This shows that they are in context and they could discuss the reality of phenomenon as well.

Through the graph construction, I asked them to organize the eye colors seen in Ali's class in order to easily realize the most and least one without counting them, for example. Their initial organizations were in Table 1 below. Four children properly formed the pictograph and they explained that they are grouping the eyes according to the colors in order to understand easily. Some of their explanations are as follows:

Hira: "We can make groups [according to color]."

Derin: "You can see which one is most and which is least in this way."

Although 3 of them (Kerem, Toprak and Emin) were not observed to form a proper pictograph initially, they used different groups of eye colors, they were mostly trying to put them in a pattern. Toprak's representation, for example, shows a nice pattern which can be seen from Table 1.

**Table 1: Initial graph constructions of participants**

Then, I asked them secondarily to organize the eyes in a different way or in order to realize the least and most one easily. Their explanations are varying differently as in the following:

Hira: "We can make a different organization, for example [she changed the direction of the cards.] (she rotated the labels 90 degrees.)"

Emin: “We can do a different graph. For example, we can put the numbers on the bars.”

Poyraz: “We can make a different graph, we can change the places of the bars, in descending order, for example.”

Kerem and Emin grouped the eyes according to the colors and constructed a proper pictograph in their second trials, as can be seen from the following Table 2. When I asked whether we can do a different organization, they both realized making groups of same colors. Although, Toprak also grouped the eyes according to colors, he couldn't represent them in an expected way. He used the bars in the same height and largened the width of the bars instead of extending the bars. Toprak, could not see different eye colors as to be comparable with each other. That is, he did not realize what a representation means or for what purpose it can be used. It can be said that he didn't understand the idea of constructing a graph and its necessity.

**Table 2: Secondary graph constructions of Kerem, Emin and Toprak**

Regarding the first question in the module, participants tended to think about the eyes in the module in comparison to their real classes. At first, 2 of them thought that Ali, mentioned in the module, was real since they have a same-name classmate as well in their classes (Ali is a common name for boys). Some of them were trying to match the eyes with their friends. For example, Hira said that her class contains only one person whose eye color is blue. This can be explained that they tried to understand Ali's situation while putting themselves in Ali's place. At the end, participants were observed that they understood the context as 'Ali's class' which is an imaginary one. That is, they could *imagine* Ali's class as it should be.

It could also be said that participants could grasp what these data tell them or not. All children could talk about Ali's friends, such as 'Ali has 5 friends who have green eyes.' Before asking the third question in the module, they could talk about these descriptive properties of Ali's class as a context.

The task designed and used in this study could be said a nice example of a suitable one which can be presented to first graders. The context was attractive for them and they were observed as they were enjoying.

## Discussion

This study showed that there is a necessity of being exposed to different statistical contexts through class activities. Based on the findings regarding the first question of the module, children were observed to making comparisons with their real-life situations in order to understand the context

presented for them. This shows that they were not accustomed to such questions in which contextual thinking brought to be forefront. As Ben-Zvi and Aridor-Berger (2016) concluded in their study that children need different types of contexts through different class activities. They need to imagine about the context which they were presented.

Regarding Makar and Rubin (2009)'s framework, it could be concluded that children could make sense of use of data as evidence and tried to make generalizations. The comparisons they made with their real classes strengthen this conclusion. For example, comparing the number of blue-eyed students in their class with Ali's class, some of them said that Ali's class has more than usual. They tried to think of the classes they have seen so far. In their school, there are two first grade classes and both class members are familiar with each other. It can also be said that the participants could analyze the data in the context (Ben-Zvi & Aridor-Berger, 2016). Therefore, the task used in this study shows a nice example of providing children to integrate data and context with each other.

The role of graph construction as another construct of informal inferential reasoning can be seen very well here in this study. Almost of the participants could realize the need to see the categories (eye colors) in the given context comparatively. Therefore, they put the first eye labels of each color in a line (horizontally or vertically) as a reference line. They were aware that their representation showed only the comparisons of categories. Suggesting some ideas like putting numbers on each bar, or reversing the graph as upside down or from right to left showed that their understandings are clear for the meaning of representation. That is, they were focused only on what conclusions could be drawn from a data representation, the pictograph in this case. Only one child focused on the pattern which he saw and he couldn't show the comparisons of categories although he responded correctly to the questions related descriptive statistics in the module. It might be because of his interest to the patterns with some objects.

This study overall could be concluded as a contribution to the existing framework for ISI of young children through graph construction. It is explaining the graph construction as a construct with an informal inferential reasoning perspective. The findings outlined here could be concluded as a contribution to the existing suggestions of integrating the statistical context structures into early childhood mathematics education with the use of data. Lastly, the findings of this study give an opportunity to the researchers in order to criticize the current situation of statistics education which was outlined above in the first part of the paper. The overall conclusions might offer a chance to deal with the ISI in the very beginning of school period of students, as well.

# What is taught and learnt on confidence interval? A case study

Kyeong-Hwa, Lee<sup>1</sup>, Chang-Geun, Song<sup>2</sup> and Yeong Ok, Chong<sup>3</sup>

<sup>1</sup>Seoul National University, South Korea; khmath@snu.ac.kr

<sup>2</sup>Seoul National University Graduate School, South Korea; riquelmes@snu.ac.kr

<sup>3</sup>Gyeongin National University of Education, South Korea; yochong@gin.ac.kr

*This study investigated what is taught and learnt with regard to relations of confidence interval and sample size when students were facilitated to reason about the graph of sampling distribution of sample means. For this aim, a teaching experiment was designed and implemented by researchers and teachers in the model of co-learning inquiry. Based on anthropological theory of the didactic, the praxeological analysis was conducted. Observed similarities and differences between the taught and learnt praxeology were discussed.*

*Keywords: Anthropological theory of the didactic, didactic transposition, confidence interval, sample size*

## Introduction

The concept of confidence interval is essential in inferential statistics. However, many students are in difficulty with understanding confidence interval (Hagtvedt et al., 2008). In particular, some research reported students' confusing on the relationship between confidence interval and other related concepts such as sample size. For example, Fidler and Cumming (2005) disclosed students' misconceptions that the width of confidence interval increases as sample size increases or is not affected by sample size. However, little research was carried on the teaching and learning of confidence interval (Pfannkuch et al., 2012).

To understand confidence interval, sample size, and their relationships, opportunities should be given for students to engage in mathematical and statistical reasoning (delMas, 2004). This study investigated what is taught and learnt regarding relations between confidence interval and sample size when students were facilitated to reason about the sampling distribution of sample means (Chance et al., 2004). For this aim, a teaching experiment was conducted in an upper secondary classroom. The framework of the Anthropological Theory of the Didactic (ATD) was used in the analysis (Bosch & Gascón, 2014). This paper reports on some preliminary results of the analysis.

## Theoretical Background

### Anthropological Theory of the Didactic

ATD is a theoretical approach characterized by its institutional perspective on mathematical knowledge. This view builds on the notion of didactic transposition (Chevallard & Bosch, 2014), which assumes that knowledge in classroom setting originates in the scholarly institution and is transformed as it adapts to different institutions. Bosch and Gascón (2014, p. 70) proposed four main institutions related to school didactic system (Figure 1). Our study focuses on the transposition between taught knowledge of teachers to learnt knowledge of students.

**Figure 1: The didactic transposition process (Bosch & Gascón, 2014, p. 70)**

In ATD, mathematical activities within each institution are modeled by the notion of *praxeology*. A praxeology consists of four intertwined elements, type of tasks ( $T$ ), technique ( $\tau$ ), technology ( $\theta$ ), and theory ( $\Theta$ ). *Type of tasks* denotes similar problems which are solved with certain *technique*. The technique is produced, justified, explained, or reasoned by the discourse named *technology*, and the technology, in turn, is justified by *theory*.

According to Bosch and Gascón (2014), researchers should take their own epistemological stance on the knowledge they address to avoid bias in the analysis. The stance is formulated as a Reference Epistemological Model (REM) and is expressed by a praxeology. We briefly introduce our REM on the concept of confidence interval below.

### REM on confidence interval

The idea of confidence interval is founded on Frequentism, as opposed to Bayesianism (VanderPlas, 2014). To the frequentist, a probability is defined as the relative frequency of occurrence of a repeatable event in the long run. In this sense, confidence intervals with  $C\%$  confidence level mean that we would expect  $C\%$  of the confidence intervals under repeated sampling to contain the fixed value of the parameter.

To illustrate the relationship between confidence interval and sample size, we further need another probability theory in our REM. The central limit theorem (Dekking et al., 2005, p. 197) implies that  $\bar{X} \sim N(\mu, \frac{\delta^2}{n})$  holds for the sample mean  $\bar{X}$ , the population mean  $\mu$ , the (known) standard deviation of population  $\delta$ , and sufficiently large sample size  $n$ . From this property, we obtain a formula,  $P\left(-z_{\alpha/2} \leq \frac{\bar{X}-\mu}{\delta/\sqrt{n}} \leq z_{\alpha/2}\right) = 1 - \alpha$ , where  $z_{\alpha/2}$  is the  $(1 - \alpha/2)$  quantile of the standard normal distribution. Behar and Yáñez (2009) introduced two logically equivalent versions of this formula:

$$P(\bar{X} - d \leq \mu \leq \bar{X} + d) = 1 - \alpha \cdots (1) \quad P(\mu - d \leq \bar{X} \leq \mu + d) = 1 - \alpha \cdots (2)$$

where  $d = z_{\alpha/2} \frac{\delta}{\sqrt{n}}$  refers to the margin of error. Formula (1) can be interpreted as the probability of the parameter  $\mu$  being in the interval  $[\bar{X} - d, \bar{X} + d]$ , called *confidence interval*, equals to  $1 - \alpha$ . Contrasting to formula (1), formula (2) represents that the probability of the sample mean  $\bar{X}$  being in the interval  $[\mu - d, \mu + d]$  equals to  $1 - \alpha$ . The probability theory shows that the probability of  $\bar{X}$  lying in the interval  $[\mu - d, \mu + d]$  is equal to the integral of probability density function of  $\bar{X}$  over the interval  $[\mu - d, \mu + d]$  (Dekking et al., 2005, pp. 57-58). The aforementioned meanings of confidence interval, confidence level, and probability equations (1), (2) constitute the theory  $\Theta$  in our REM.

Building on the theory  $\Theta$ , we can consider two techniques and their technology about the type of tasks of finding the relationship between the width of confidence interval and sample size. Based on the

formula (1), the first technique  $\tau_{algebra}$  refers to applying the equation  $l = (\bar{X} + d) - (\bar{X} - d) = 2z\alpha/2 \frac{\delta}{\sqrt{n}}$ , which is often found in curriculum materials (e.g. Lee et al., 2011, p. 181). By proportional reasoning (Post et al., 1988), which includes interpreting of the algebraic representation of proportionality ( $\theta_{algebra}$ ), it is explained that the increasing sample size  $n$  decreases width of confidence interval. Another technique  $\tau_{graph}$  can be found on the formula (2).  $\tau_{graph}$  refers to comparing the area under graphs of sampling distribution within  $[\mu - d, \mu + d]$  for different sample sizes. This technique requires justification by reasoning about statistical or probabilistic idea including “describing what a sampling distribution would look like for different sample sizes based on shape” ( $\theta_{graph,1}$ ) and “interpreting areas under the sampling distribution curve as probability statements about sample means”. ( $\theta_{graph,2}$ ) (Chance et al., 2004, p. 301). Also, the explanation about relations between  $[\mu - d, \mu + d]$  and confidence interval is included in the technology (Behar & Yáñez, 2009) ( $\theta_{graph,3}$ ). These kinds of technology should be integrated to justify  $\tau_{graph}$  as follows. Since the spread of sampling distribution decreases as sample size increases, the margin of error  $d$  satisfying the area under the sampling distribution over  $[\mu - d, \mu + d]$  equals to  $1 - \alpha$  become smaller as sample size increases and, accordingly, confidence interval  $[\bar{X} - d, \bar{X} + d]$  become narrower as sample size increases.

## Method

This study is qualitative research performed through a case study of a designed teaching experiment (Yin, 2014). We choose our design-based research methodology based on the model of *co-learning inquiry* (Jaworski, 2004). In this model, teachers are treated as *partners* of researchers rather than passive participants of research, and teachers and researchers collaboratively design, implement, and evaluate lessons in the iterative process. The main power of co-learning inquiry model is that the result of the research can contribute to “sustainable new practices” of teachers, since “teachers engage in their own purposeful activity” in this model (ibid., p. 19).

Participants in this study were a high school teacher from a public upper secondary school in Korea and his 35 students. Around the topic of statistical inference, five lessons were designed and implemented. Audio and video recordings of the lessons and students’ worksheets were collected.

In this study, we analyzed the last lesson of which learning objective was to understand the relations among confidence interval, confidence level, and sample size. We emphasize that students were encouraged to use graphs of sampling distribution to explain these relations. The collected data were analyzed by praxeological analysis (Bosch & Gascón, 2014). The focus of the analysis was on the didactic transposition between taught knowledge to learnt knowledge about relations between confidence interval and sample size. Based on our elaborated REM on confidence interval (Table 1), we analyzed the four elements of the taught and learnt praxeology and revealed their similarities and differences. The designed activities were interpreted as *type of tasks* in ATD sense. The teacher’s utterance and the teaching materials were mainly analyzed to figure out the other components of the taught praxeology. On the other hand, worksheets of students and their audio recordings were analyzed to find out the learnt praxeology. In particular, students’ answers on the following task were analyzed to describe technique, technology, and theory parts of the learnt praxeology: *Consider three*

confidence intervals with 90% of confidence level. Size of each sample is 4, 25, and 100. Array these intervals according to their width. Explain your answer using sampling distributions.

Type of tasks	$T$ : To find the relations between the width of confidence interval and sample size
Technique	$\tau_{algebra}$ : To apply $l = 2z_{\alpha/2} \frac{\delta}{\sqrt{n}}$ (Lee et al., 2011, p. 181) $\tau_{graph}$ : To compare the area under graphs of sampling distribution function within $[\mu - d, \mu + d]$ for different sample sizes
Technology	$\theta_{algebra}$ (for $\tau_{algebra}$ ): Proportional reasoning (Post et al., 1988) $\theta_{graph,1}$ (for $\tau_{graph}$ ): Reasoning about the impact of sample size on graphs of sampling distribution (Chance et al., 2004) $\theta_{graph,2}$ (for $\tau_{graph}$ ): Graphical interpretation of probability statements about sample means (Chance et al., 2004) $\theta_{graph,3}$ (for $\tau_{graph}$ ): Explanation about relations between $[\mu - d, \mu + d]$ and confidence interval (Behar & Yáñez, 2009)
Theory	$\Theta$ : The meaning of confidence interval and confidence level (VanderPlas, 2014); the meaning of $P(\bar{X} - d \leq \mu \leq \bar{X} + d) = 1 - \alpha$ and $P(\mu - d \leq \bar{X} \leq \mu + d) = 1 - \alpha$ (Behar & Yáñez, 2009)

**Table 1: REM on confidence interval**

## Result

### What is taught?

Two taught praxeology  $\wp_1$ ,  $\wp_2$  were revealed in the lesson. The components of  $\wp_1$  are summarized in Table 2.

Type of tasks	Empty
Technique	Empty
Technology	Graphical interpretation of probability statements about sample means ( $\theta_{graph,2}$ ) Explanation about relations between $[\mu - d, \mu + d]$ and confidence interval ( $\theta_{graph,3}$ )
Theory	The meaning of confidence interval with confidence level; The meaning of $P(\bar{X} - d \leq \mu \leq \bar{X} + d) = 1 - \alpha$ and $P(\mu - d \leq \bar{X} \leq \mu + d) = 1 - \alpha$ ( $\Theta$ )

**Table 2: Components of the taught praxeology  $\wp_1$**

$\wp_1$  was a local know-how which consisted of only technology and theory parts. The theory part of  $\wp_1$  included the meaning of probability statements of sample means,  $P(\bar{X} - d \leq \mu \leq \bar{X} + d) = 0.95$  and  $P(\mu - d \leq \bar{X} \leq \mu + d) = 0.95$ . The meaning of each statement together with confidence interval and confidence level was explained by the teacher in the sense of Frequentism.

Teacher: As you can see, among 100 confidence intervals, only 5 do not contain and the other 95 contain (the population mean). ... It means that the level of confidence is 95%.

Grounded on the meaning of probability, the relations between  $[\mu - d, \mu + d]$  and confidence interval  $[\bar{X} - d, \bar{X} + d]$  were explained. Graphic representation of the probability statements  $P(\bar{X} - d \leq \mu \leq \bar{X} + d) = 0.95$  and  $P(\mu - d \leq \bar{X} \leq \mu + d) = 0.95$  was used with the explanation.

Teacher: Here's the summary. The probability of  $\bar{X}$  being contained between  $\mu - d$  and  $\mu + d$  is equivalent to the probability of population mean contained in this one ( $[\bar{X} - d, \bar{X} + d]$ ). [PowerPoint slides that teacher used with this explanation. Numbers in slides were chosen from an exercise without contextual meanings.]

Although the technology and theory part of  $\wp_1$  ground the robust foundation for its potential practice, this praxeology was ‘in a vacuum’ in that “what kind of problems it can help to solve” is not known (Barbé et al., 2005, p. 237).

Table 3 describes components of another taught praxeology  $\wp_2$ .

Type of tasks	To compare the probability of sample mean being in a given range when graphs of sampling distribution with different (hidden) sample sizes are given
Technique	To compare the shape of graphs and area under graphs of sampling distribution within a given range ( $\tau'_{graph}$ )
Technology	Reasoning about the impact of sample size on graphs of sampling distribution ( $\theta_{graph,1}$ ) Graphical interpretation of probability statements about sample means ( $\theta_{graph,2}$ )
Theory	Empty

**Table 3: Components of the taught praxeology  $\wp_2$**

$\wp_2$  was organized around a type of tasks, to compare the probability of sample mean being in a given range when graphs of sampling distribution with hidden sample size (4, 25, 100) are given. The technique  $\tau'_{graph}$  of  $\wp_2$  consisted of two subsequent sub-techniques. The first sub-technique was to compare the shape of sampling distribution function to figure out hidden sample sizes. This sub-technique was justified by the technology  $\theta_{graph,1}$ , which was the discourse about the impact of sample size on graphs of sampling distribution. The following sub-technique was to compare the area under the graphs of sampling distribution. This sub-technique required interpreting areas under the sampling distribution curve as probability statements about sample means ( $\theta_{graph,2}$ ).

One may note that the technique  $\tau'_{graph}$  is slightly different from  $\tau_{graph}$  in that  $\tau'_{graph}$  did not require the explanation about confidence interval. Hence, the technology and theory related to the concept of confidence interval were missing in  $\wp_2$ . The theory about probability sentences was also void in  $\wp_2$ , which made the theory part of  $\wp_2$  empty.

### What is learnt?

The praxeology of the taught and learnt praxeology are summarized in Table 4.

	Taught praxeology ( $\wp_1, \wp_2$ )	Learnt praxeology
Type of tasks	- To compare the probability of sample mean being in a given range ( $\wp_2$ )	- To find the relations between the width of confidence interval and sample size
Technique	- To compare the shape of graphs and area under graphs of sampling distribution within a given range ( $\tau'_{graph}, \wp_2$ )	- To apply $l = 2z_{\alpha/2} \frac{\delta}{\sqrt{n}}$ ( $\tau_{algebra}, 8\%$ ) - To compare the area under graphs of sampling distribution within $[\mu - d, \mu + d]$ for different sample sizes ( $\tau_{graph}, 85\%$ )
Technology	- Reasoning about the impact of sample size on graphs of sampling distribution ( $\theta_{graph,1}, \wp_2$ ) - Graphical interpretation of probability statements about sample means ( $\theta_{graph,2}, \wp_1, \wp_2$ ) - Explanation about relations between $[\mu - d, \mu + d]$ and confidence interval ( $\theta_{graph,3}, \wp_1$ )	- Proportional Reasoning ( $\theta_{algebra}, 8\%$ ) - Reasoning about the impact of sample size on graphs of sampling distribution ( $\theta_{graph,1}, 85\%$ ) - Graphical interpretation of probability statements about sample means ( $\theta_{graph,2}, 48\%$ )
Theory	- The meaning of confidence interval with confidence level; The meaning of $P(\bar{X} - d \leq \mu \leq \bar{X} + d) = 1 - \alpha$ and $P(\mu - d \leq \bar{X} \leq \mu + d) = 1 - \alpha$ ( $\Theta, \wp_1$ )	Empty

**Table 4: Components of the taught and learnt praxeology**

Although the taught praxeology  $\wp_1$  and  $\wp_2$  did not contain  $\tau_{algebra}$  as a technique, some students (8%) used  $\tau_{algebra}$  to explain the relationship between the width of confidence interval and sample size. For example, a student explained that his technique  $\tau_{algebra}$  was justified “since the width of confidence interval equals to  $2 \times a \times \frac{\delta}{\sqrt{n}}$ , the width becomes smaller as  $n$  increases”. This kind of justification corresponds to proportional reasoning  $\theta_{algebra}$ .

Excluding non-replied answers, remaining 30 students (85%) applied  $\tau_{graph}$ . However, their technology differed in degree (Figure 2). 13 students (37%) only relied on the reasoning about the impact of sample size on the shape of sampling distribution ( $\theta_{graph,1}$ ). The other 17 students (48%) could integrate  $\theta_{graph,1}$  with  $\theta_{graph,2}$  when they justified their technique. These two technological elements were also found in the taught praxeology  $\wp_2$ . However,  $\theta_{graph,3}$ , which was another technological element of the taught praxeology  $\wp_1$ , was missing in the learnt praxeology even though  $\theta_{graph,3}$  was essential to fully justify technique  $\tau_{graph}$  of the learnt praxeology.

[Sampling distribution of the sample means is more spread out with the smaller sample size (left)]

**Figure 2: Examples of  $\tau_{graph}$  with  $\theta_{graph,1}$  (left) and  $\tau_{graph}$  with  $\theta_{graph,1}$  and  $\theta_{graph,2}$  (right)**

The meaning of confidence interval and confidence level (in the sense of Frequentism) was implicit in students' worksheets or in their dialogues. Moreover, the expression  $P(\bar{X} - d \leq \mu \leq \bar{X} + d) = 1 - \alpha$  or  $P(\mu - d \leq \bar{X} \leq \mu + d) = 1 - \alpha$  was hardly dealt with in students works, which leads to the theory part of learnt praxeology lacking the meaning of those expressions.

## Discussion

In this study, we analyzed what is taught and learnt in a didactic setting which encouraged reasoning about sampling distribution. Some notable similarities and differences between them were observed.

Firstly, technology  $\theta_{graph,1}$  and  $\theta_{graph,2}$  were both taught and learnt in the classroom setting. Agreeing with Chance et al. (2004, p. 300) that  $\theta_{graph,1}$  and  $\theta_{graph,2}$  are kinds of reasoning “students should be able to do with their knowledge of sampling distributions”, we argue that essential reasoning about sampling distribution could be integrated in the teaching of relationships between confidence interval and sample size. Furthermore, this kind of reasoning would contribute to the understanding of the relationship between confidence interval and sample size since the notion of sampling distribution and its representation are closely related with each of those concepts.

Secondly,  $\theta_{graph,3}$  as well as theory underneath it were found in the taught praxeology but were entirely implicit in the learnt praxeology. These technology and theory were only contained in the local know-how  $\wp_1$ . Similar phenomenon was also appeared at Barbé et al. (2005) in the case of teaching of limits of functions. We infer that the reason of the incongruity between the taught and learnt praxeology was partly because the related practice of the taught praxeology  $\wp_1$  was unknown. Hence, we expect that another taught praxeology with a concrete task whose technique is justified by  $\theta_{graph,3}$  and its theory would derive more strict discourse in learnt praxeology.

Finally,  $\tau_{algebra}$  with  $\theta_{algebra}$  was not taught but learnt in this lesson. This result shows the potential that diverse techniques, including  $\tau_{algebra}$  and  $\tau_{graph}$ , could be employed in the activity of searching relations between confidence interval and sample size. Discussing different techniques and their technology, different local praxeology of students could be connected and integrated into regional praxeology (Bosch & Gascón, 2014).

The research was funded by the Korean Ministry of Education and the National Research Foundation of Korea (NRF-2016S1A5A2A01024273)

# Prospective high school teachers' interpretation of hypothesis tests and confidence intervals

M<sup>a</sup> del Mar López-Martín, Carmen Batanero and María M. Gea

University of Granada, Spain; [mariadelmarlopez@ugr.es](mailto:mariadelmarlopez@ugr.es), [batanero@ugr.es](mailto:batanero@ugr.es), [mmgea@ugr.es](mailto:mmgea@ugr.es)

*This research aims to assess the interpretation of results by prospective high-school teachers when performing hypothesis tests and confidence intervals. The responses given by 73 prospective Spanish teachers to an open problem from the university entrance tests were analyzed. Although the majority of participants correctly performed many of the steps in both procedures, only a proportion of them were able to interpret and contextualize the results. The obtained results show that prospective teachers need to be prepared for this topic in order to develop inferential reasoning in their students.*

*Keywords: Hypothesis tests, confidence intervals, content knowledge, prospective teachers.*

## Introduction

Statistical inference plays a prominent role in human science research and it is a subject covered in the Spanish high-school curriculum (MECD, 2015) as well as in university entrance exams, which have included an inference problem for each of the last 15 years (López-Martín, Batanero, Díaz-Batanero, & Gea, 2016). This topic is not easy, as shown by research describing the errors that students make (Castro Sotos, Vanhoof, den Nororgate, & Onghena, 2007; Makar & Rubin, 2018). Improving understanding and application of the topic involves adequate preparation for the teachers who are responsible for teaching it; this point has barely been considered in previous research (Harradine, Batanero, & Rossman, 2011, Makar & Rubin, 2018). The aim of this study is to complement previous research by analysing the results interpretation of simple statistical tests and confidence intervals carried out by prospective teachers. The interpretation of statistical data and results is suggested in the high school Spanish curriculum (MECD, 2015).

## Previous research

Previous statistical test research has reported on interpreting errors regarding the  $\alpha$  significance level and the p-value, where students change the two conditional probability terms in their definition (Falk & Greenbaum, 1985), or interpret these concept levels as the probability of being wrong when rejecting the null hypothesis (Vallecillos, 1999). Other conspicuous errors include: the role played by the null and alternative hypotheses (Batanero, 2000), confusion between unilateral and bilateral tests, defining hypotheses that do not cover the parametric space, and using the sample statistic instead of the population parameter to define the hypotheses (Vallecillos, 1999; Vera, Díaz, & Batanero, 2011). In regards to confidence intervals, students ignore their inferential character (Behar, 2001; Olivo, 2008) or misinterpret the relationship between the different factors influencing the width of the confidence interval (Cumming & Fidler, 2005).

Some research work focusing on teachers' understanding of inference suggests that certain teachers share the same misconceptions as the students. Haller and Krauss (2002) describe errors in understanding the significance level and p-values, as was the case with some prospective teachers

taking part in the Vallecillos research. After interviewing 8 high-school statistics teachers, Liu and Thompson (2009) suggested that they seemed not to understand the purpose of statistical tests as mechanisms for carrying out statistical inference. They also found that the teachers' conception of probability was not grounded in the concept of sampling distribution being the fraction of time that a statistic's value is within a particular range. While recent research studies have attempted to organise teachers' education in terms of informal inferential reasoning, some of them (e.g. Dolor & Kirin, 2018) suggest that prospective teachers use incorrect strategies to compute p-values in re-sampling and simulation approaches; although they also suggest that adequate training may improve these strategies.

Nowadays, statistical interpretation is considered a complex process involving cognitive, affective and technical aspects (Queiroz, Monteiro, Carvalho, & François, 2017). Wild and Pfannkuch (1999) included the integration of statistics and contexts (that is to say, results interpretation) as part of their statistical thinking model. Monteiro (2005) developed the idea of critical sense during the interpretation of statistical graphs, which includes mathematical knowledge, contextual references, affect and personal experiences related to the data. In this work, we analyse prospective teachers' interpretations of the hypothesis test and confidence interval.

## Method

The sample group was made up of 73 students on a Master's Degree course that is compulsory for those who intend to become high-school mathematics teachers in Spain. Of these, 56% were graduates in Mathematics or Statistics while the remainder had completed undergraduate studies in Engineering, Architecture or Science. All of them had taken some statistics courses during their undergraduate studies and 57% had some teaching experience. Most of participants recognized that the methodology used focused on teaching procedures rather than the use of technology. The assessment was part of an activity aimed at developing the participants' content knowledge of inference. The participants worked on authentic data obtained from the United Nations. In this paper, we analysed the participants' solutions to the following problem.

**Problem:** The average life expectancy in a study developed by the United Nations is 69.2 years with a standard deviation 10. In a random sample of 16 European countries, the average life expectancy was 78 years. Assuming that the life expectancy follows the normal distribution:

- a) Propose and interpret a hypothesis test, with a level of significance of 5%, to analyse if the average life expectancy in Europe is higher than that obtained in the whole set of countries;
- b) Determine and interpret a 95% confidence interval for average life expectancy in European countries.

We performed a qualitative analysis on the written solutions to the problem in order to classify the responses into different categories, starting with previous research and refining the categories through a cyclic and inductive process; this is typical of qualitative research. Below, we first summarise the general performance in each part of the problem using a numerical score, and then we analyse the participants' interpretation of the research for each procedure in detail.

## Results

### General performance in solving the problems

The solution to part a) involved a unilateral hypothesis test on the average of a normal population with a known variance; this is an element included in the compulsory examination to become a high-school mathematics teachers as well as in the curricular guidelines for high-school and university entrance examinations in Spain. By analysing the participants' answers, we examined the prospective teachers' knowledge of the following points: a) the way they established the test hypotheses; b) whether the problem-solving procedure employed was consistent with the hypotheses proposed; c) the computation of the p-value; d) other possible errors in the procedure not listed yet; and e) the interpretation of the results. In order to graduate the prospective teacher's knowledge about the hypothesis contrast, we have marked each participants with a score according to the number of correct answers. This score would be from 0 to 5 points, one point for each correct answer (Figure 1).

Most prospective teachers were able to correctly develop three or more steps, although 6 participants incorrectly developed all the stages in part a) of the problem. Although 67% of the students set correct hypotheses, only 4% selected a test that was consistent with the hypotheses. We would like to point out that only 51 participants computed the p-value, and some of them made errors in either the computation or in other parts of the procedure. Only 38.4% of participants correctly interpreted and contextualised the results.

**Figure 1. Percentage and cumulative percentage of participants according to the number of correct steps in performing a hypothesis test**

The solution to part b) involved a confidence interval for the average of a normal population with a known variance. By analyzing the participants' answers, we examined the prospective teachers' knowledge of the following points: a) the way they established the interval; b) whether the problem-solving procedure they followed was correct and c) the interpretation of the results. By awarding a point to each of these parts of the hypothesis test solution, participants could score from 0 to 3 points (Figure 2). We observed that 46.6% of them correctly solved two of the stages (85% developed points a) and b) whilst the rest developed points a) and c)) and 16 prospective teachers gave correct answers for all the parts.

In summary, these results suggest a moderate knowledge of statistical tests and confidence intervals on the part of teachers in our sample, which is a matter of concern, given that these teachers have to prepare their students in this topic to face the entrance to university tests where an inference problem is included every year.

Below we analyse in depth the final interpretation that prospective teachers perform in each part of the problem, that is, the way they interpret the results of the test and that of confidence interval.

**Figure 2. Percentage and cumulative percentage of participants according to the number of correct steps in computing a confidence interval**

### Interpreting statistical tests

Once the calculations were completed, we expected participants to conclude that the result in part a) was statistically significant and that the null hypothesis should be rejected. When contextualizing this result, the conclusion was that we should reject the hypothesis that the average life expectancy in Europe is the same (or smaller) than that in the group of countries. By taking into account the correctness of the decision and the contextualization made, we defined the following categories:

*C1. Correct decision and contextualization.* Prospective teachers made an appropriate decision and related the result to the problem's context, as in the following example:

GPF: When comparing the small p-value with the significance level of  $\alpha=0.05$ , it is reasonable to reject the null hypothesis and conclude that life expectancy in Europe is higher than in the set of countries.

*C2. Correct decision and contextualization but the p-value is interpreted as the probability of the hypothesis.* Although the decision and contextualization were correct, there was an incorrect interpretation of the p-value, which concluded that the null hypothesis was probably correct, such as in BCM's answer.

BCM: In summary, the average life expectancy in Europe is higher than the average life expectancy in the set of countries, with a probability equal to 0.9998.

*C3. Correct decision and contextualization, assuming that the null hypothesis is false.* Although the decision and contextualization were correct, there was a deterministic conception of the result that assumed the null hypothesis to be false; an error described by Inzunsa and Jiménez (2013) and Vallecillos (1994):

ALP: [...] we conclude that the null hypothesis is false, so we accept that the average life expectancy in Europe is higher than the average life expectancy in the set of countries with a probability significance level of 0.05.

*C4. Correct decision with inconsistent contextualization* (see the response by ILG):

ILG: We reject the null hypothesis so the average in Europe cannot be higher than that in the set of countries.

In the following categories, the students made a correct decision with no contextualization (C5; see the response by AGS), explaining how to make the decision (but with no decision being made) and either by contextualising (C6) or not contextualising (C7), made an incorrect decision (C8; see the response by JGM) or did not make a decision (C9):

AGS: [...] for  $Z=3.52$ , we get 0.99998; by subtracting this from 1, we obtain a probability of 0.0002 and, therefore, reject the hypothesis.

JGM:  $H_0$  = the average life expectancy in Europe is greater than the average life expectancy in the rest of the countries. [76.78; 79.23].  $H_0 \rightarrow$  Not rejected, since the average value for the set of countries is below the values of the confidence interval for a confidence level of 95% for the sample of European countries.

In Table 1, we present the participants' interpretation of the statistical tests, where less than 40% made the right decision and contextualized the problem; nonetheless, 86.2% made the right decision. The remaining participants either did not make a conclusion or decided incorrectly. Some showed that they misunderstood the hypothesis tests; for example, assuming that the p-value indicated that the null hypothesis was probably true or holding a deterministic view of the results.

Code	Interpreting the results	Frequency	Percentage
C1	Correct decision and contextualization	28	38.3
C2	Correct, interpret p-value as the probability of the hypothesis	3	4.1
C3	Correct, assuming that the null hypothesis is false	2	2.7
C4	Correct, no appropriate contextualization	6	8.2
C5	Correct, does not contextualise	24	32.9
C6	Describing how to make the decision and contextualising	1	1.4
C7	Describing how to make the decision and not contextualising	7	9.6
C8	Incorrect decision	1	1.4
C9	Making no decision	1	1.4

**Table 1: Frequency and percentage of participants according interpretation of statistical tests**

### **Interpreting the confidence interval.**

Once the confidence interval extremes were computed, we expected the prospective teachers to provide an interpretation such as follows: For a 95% confidence interval computed from 16 sample elements, in about 95 of them, the average life expectancy in European countries would be included; that is to say, they should have interpreted the interval extremes as being random variables (Behar, 2001; Olivo, 2008). We found the following response categories:

*C1. Correct interpretation.* Here, we classified the correct responses given above, and variations of the same, along with those that indicated the percentage of intervals computed from different samples that included the parameter (Behar, 2001); see CBF's answer:

CBF: [...] this is the probability that a number of intervals cover the parameter, not that the parameter is included in the actual interval.

*C2. Determinist interpretation.* When the participant interprets the interval in a deterministic way, they do not appreciate the randomness of the extremes (Olivo, 2008):

DAM: This means that the average life expectancy in European countries is between 73 and 83.

*C3. Interpreting the confidence level as the probability that the parameter is included in the interval.* The confidence level is interpreted as the probability that the population parameter is within the range obtained. Authors like Behar (2001) and Olivo (2008) have analysed this misunderstanding:

LUG: You can conclude that the probability that the population average is included in the interval is 95%.

*C4. Assuming that the sample average is included in the interval.* Another mistake is interpreting that the confidence interval includes the sample average instead of the population average, which also signifies confusion between the statistics and the parameter:

JGM: 95% of intervals computed from samples of European countries will include the sample mean.

The results are presented in Table 2, where the participants' difficulty in interpreting the confidence interval information is evident. Only around 30% gave a correct interpretation whilst the majority were unable to provide an interpretation, and the remaining participants either interpreted the confidence intervals in a deterministic way or reproduced one of the errors described in previous research.

Code	Interpreting the results	Frequency	Percentage
C1	Correct interpretation	21	28,8
C2	Deterministic interpretation	8	11,0
C3	Interpreting $1 - \alpha$ as the probability that the parameter is included in the interval	13	17,8
C4	Assuming that the sample average is included in the interval	1	1,4
C5	Do not interpret	30	41,1

**Table 2. Frequency and percentage of participants according interpretation of confidence intervals**

### **Implications for teaching and research**

Our results suggest a need to improve the education of prospective Spanish high-school teachers in terms of teaching statistical inference. On the one hand, few in the sample group correctly

performed all the steps for solving the statistical tests or the confidence interval, even when the problem posed was similar to those included in the Spanish university entrance tests.

Similar to previous research, many were unable to properly interpret the results of the procedure, made incorrect decisions in the statistical tests or gave responses that reproduced different errors, h. Although many made correct decisions in the statistical test, few interpreted the result in the context of the problem - this is worrisome because teachers are expected to develop their students' ability to interpret statistical studies; for example, one learning goal in the curriculum (MECD, 2015, pp. 398 and 407) is: "To interpret a statistical study based on situations close to the student."

Therefore, in addition to improving prospective teachers' mathematical knowledge of inference, it is necessary to prepare them to be able to contextualize the information resulting from statistical tests and confidence intervals so that they can help their future students acquire this interpretative capacity. Of course, mathematical knowledge alone is not enough for teaching success. It is necessary to continue this analytical research into pedagogical knowledge regarding statistical inference. In this regard, several studies have shown that an informal approach to statistical inference could help in understanding the logic involved and improve the teaching process. We hope these questions will interest teacher trainers and other researchers in statistical education, and that we can ensure the good mathematical and didactic training of high-school teachers so that they can successfully teach statistical inference to their future students.

# Covariational reasoning patterns exhibited by high school students during the implementation of a hypothetical learning trajectory

Miguel Medina, Ernesto Sánchez and Eleazar Silvestre

Departamento de Matemática Educativa, CINVESTAV-IPN, Mexico

[ingcivi\\_6@yahoo.com.mx](mailto:ingcivi_6@yahoo.com.mx), [esanchez@cinvestav.mx](mailto:esanchez@cinvestav.mx), [eleazar.silvestre@gmail.com](mailto:eleazar.silvestre@gmail.com)

*We report some evidences of an ongoing research on covariational reasoning with high school students concerned with the design and application of a Hypothetical Learning Trajectory (HLT) on problems of correlation and linear regression, as well as the role played by technology (Fathom) employed in the learning process. We observed student's performance was slightly better when using the software in the instructional sequence, such as identifying and using the correlation strength and elaborating more refined arguments when comparing their own estimated model against the least squares line.*

*Keywords: Covariational reasoning, linear regression and correlation, high school, Fathom*

## Context and research question

Research by psychologists and statistical educators have produced extensive and robust knowledge about students' covariational reasoning; for example, Zieffler and Garfield (2009, p. 11) summarized the general research findings in six statements: students are often, 1) significantly influenced by their personal beliefs with respect to their covariational judgments; 2) prone to believe that correlation exists where there's actually none; 3) only considering data that support the joint presence of variables but ignore those referring to joint absence of variables; 4) greatly challenged to grasp negative correlation than dealing with a positive one; 5) disposed to make estimates below the actual correlation's strength; and 6), susceptible to imply causal relationships when dealing with covariation tasks. In contrast, it's more difficult to find research reports on how to produce progressive changes in students' covariational reasoning as a result of teaching interventions in classroom, including why such changes would occur. In a recent literature review performed by the authors during the past 10 years, only five reports were found that include teaching interventions, two of which were carried out with tertiary level students (Inzunza, 2016, McLaren, 2012), two at high school level (Gil & Gibbs, 2017; Dierdorp, Bakker, Eijkelhof & van Maanen, 2011) and one at elementary level (Fitzallen, 2012). Such amount of investigations that report on the effects of instruction in students' covariational reasoning reflect Shaughnessy and others' recommendations for future statistical educational research, who highlighted the need to carry out teaching experiments and document the effects of instruction. On the other hand, regarding research on the development of scientific thinking, students' covariational reasoning has been widely investigated at the elementary and middle school levels (Zimmerman, 2007) but rarely at the high school level (even considering replica with adult subjects); in addition, the attended statistical content in most of these studies is mainly restricted to the association between qualitative variables. Thus, the results of our research aim to strengthen the body of knowledge on covariational reasoning within this particular trend.

In Mexico, the topic of numerical bivariate data, correlation and line of better fit is prescribed for most high school curricula, in which is common to find the use of dynamic statistical technology tools (e.g., Excel or Fathom) as a resource that could play a fundamental role in producing progressive changes in students' reasoning; in particular, technology can help promote covariational reasoning because it allows students to optimize the time it takes to make a graph and relieves the burden of making complex calculations. Given this context, the purpose of this study is to identify patterns in students' reasoning emerged from the implementation of a developing hypothetical learning trajectory about linear regression and correlation; we propose a research question consistent with the following analysis strategy: to determine and compare reasoning patterns with some previously detected in an exploratory-diagnostic study where no teaching intervention was performed. Therefore, the new progressive patterns provide cues to the achievements gained during the new teaching strategy, so that our research question becomes: *What reasoning patterns emerge in students' solutions to problems of correlation and line of best fit during and as a result of student participation in a learning trajectory that includes extensive use of Fathom?*

### Conceptual framework

We rely on three fundamental ideas: (1) *covariational reasoning*, (2) the notion of *aggregate*, and (3) the mechanism of a *hypothetical learning trajectory*. Covariational reasoning is characterized as thinking process carried out by the subjects related to judgments and interpretations about the relationship that exists between two variables. Carlson, Jacobs, Coe, Larsen & Hsu (2002) indicate that covariational reasoning is defined as the cognitive activities included in the coordination of two quantitative variables while attending to the ways in which they change one with respect to the other; this type of reasoning also entails understanding many features of variation in which variation with respect to the linear fit model is highlighted. Some studies discuss the modeling of variation and the importance of considering both explained and unexplained variation when data is explored; these two characteristics of variation are of particular interest in the study of the linear regression between two quantitative variables because the isolation and modeling of aspects of variation allows to carry out predictions, explanations and control, as well as to question why variation occurs resulting in the search for its causes.

In a linear regression and correlation context, the notion of aggregate is related to the form in which learners perceive a bi-variate data set through its representation in a scatterplot, and it's also related with the objectives of interpreting the possible relation that exists between the variables that generate the data, propose a linear model that best fits the data and estimate new values for the response variable within the available data set. Bakker (2004) and Dierdrop et al. (2011) highlighted the importance of such notion in students' learning process since it allows for drawing conclusions about regression and correlation given that it is through this reasoning that one can identify trends that extend beyond the correlated data; that is, to assume the notion of aggregate as to set a structure opposed to the attributes that could be addressed to aisled data points.

Finally, the notion of an HLT was introduced by Simon (1995) as an essential component of a constructivist teaching and learning posture. The mechanism involves the selection and dynamic interaction between three main components: learning objectives, a set of mathematical tasks, and the associated learning hypotheses as a prediction of students' actions and reasoning in response to

the activities. We intend to employ such mechanism in our research both as a device for planning didactic interventions as well as a research vehicle, which requires a cycling revisiting of the three mentioned elements grounded in students' practices and reasoning patterns.

## Method

*The previous study, constructing the HLT.* Learning activities of the HLT are based on a questionnaire applied in 2016 to two groups of high school students enrolled in their senior year (17-18 years) in a public school; a total of 96 students participated in the study (Medina, Olay & Sánchez, 2016). From the analysis carried out in this exploratory test, students' responses to the problems (described up next) exhibited the following main learning obstacles:

- Students do not assume the data set as a whole, as an aggregate with its own properties, but as isolated cases with independent ones; to draw a line of best fit, they do not consider the variation that exists between the data and the position the model should have, and tend to only consider some points of the data available (such as the first and last ones, or the highest and lowest values of the set).
- The idea of creating a diagram to represent the bivariate data does not arise intuitively; students don't clearly identify properties such as the intensity of the relationship between the variables nor the meaning of the data pairs; and when facing prediction problems, do not use statistical concepts but rely heavily on arithmetic procedures.

Based on the difficulties encountered in this study, learning hypothesis for the design of the HLT were developed: students should be able to convert data collected in tables to a graphic representation (scatter plot diagram); reflect on how to use all data when proposing their line of best fit; understand and discuss the meaning of the line of best fit as the line that minimizes the estimation error; consider the development of a scatterplot as a necessary tool for the analysis of the relationship between two variables; make hypotheses about the relationship between two variables (graduated: none, little, lots of) based on the analysis of a scatter plot diagram; and obtain the least squares linear model to determine the value of the requested response variable. These hypotheses were condensed in two main learning objectives, (1) the *learning about distributions of bivariate data*: which intends for students to identify what elements, like the form and the tendency of a cloud of data points, are determining to establish the type of relation that exists between two quantitative variables, and (2), the *learning about the variation of the data with respect to the linear adjustment model*: which intends for students to identify that the linear adjustment model has an intrinsic random character rooted in the data itself.

*Participants, instruments and execution.* The current version of the HLT was applied to a group of 40 students (15 males, 25 females; 17-18 years old), arranged in 20 pairs, also enrolled in their senior year on a public high school in Mexico City; they previously received instruction on some essential descriptive statistics topics (statistical graphs, tendency and variability measures) and a mild technical-procedural introduction to linear regression and correlation. The application of the experiment consisted of 4 sessions of approximately 2 hours each: students familiarized with Fathom's basic commands with an instruction activity during the first session; in session 2, students faced the *gas consumption* problem [adapted from Moore, 1998; item (i), figure 1] in which they

proposed their line of best fit using the software, as well as analysis of some characteristics of the possible correlation between the variables (intensity and direction); such evidence which allowed the researchers to produce detailed descriptions of the visual analysis performed by the students and their justifications.

**Figure1: Data used in the gas consumption problem [(i), left], and in the arm and height measures problem [(ii), right]**

This is, students were asked about the form of the distribution of the data in the scatter plot, with which they could propose their own linear model that best fit the data (all of the instruction required the use of Fathom). In session 3, a further investigation of this problem was performed by adding a prediction item and a comparative analysis of the least squares line provided by the software against the students' own model. Finally, in session 4, students faced the *height and arm measures* problem [item (ii), Figure 1], in which data was produced and taken by and from a sample of the participants. Once again, besides comparing students' own model against the least squares line, the value corresponding to the sum of squares (errors) was provided through the software as a variability measure between the data and the linear models.

*Data and analysis tools.* Our primary source of data are students' written responses to the activities, fieldnotes and video recordings. We rely on principles and basic coding techniques provided by the *Grounded Theory*, which emphasizes the creation of categories and emergent theory based on the data that is systematically and exhaustively collected during the investigation. Analysis of students' responses consisted of identifying patterns exhibited in at least two pairs of students (open and axial coding); each one was given a code defined below, leading to ten emergent codes assigned into one of three groups: *inconsistent*, *favorable* or *neutral*; these adjectives refer to their relationship with normative covariational reasoning. Inconsistent codes correspond to reasoning features that we consider difficult the understanding of normative ideas embedded in covariational reasoning, while favorable codes prefigure or constitute partially aligned basis for normative reasoning considering that additional teaching support can help to overcome; neutral codes refer to those which we didn't find reasons to be classified as neither of the former.

## Results

Inconsistent codes are labelled A1-A5, favorable are labelled B1-B4, and the only neutral corresponds to C1; we now briefly describe and exemplify these codes using the notation "PX" to denote a specific pair of students' response.

A1. *Illusion of linearity (or proportionality)*. When confronted with a prediction problem, it consists of proposing a plausible value of  $Y$  given a value  $x_0$ , a specific point of the data set is chosen to formulate and apply a rule of three. An example of this reasoning comes with P8's response (gas consumption problem): "We applied a rule of three with the average temperature of 10.7 cause is the closest to 8,  $\frac{10.7m^3}{10.7^\circ}(8^\circ) = 8m^3$  of gas".

A2. *Incidence in the maximum amount of points*. To determine the line of best fit, a line that goes through the maximum number of points is proposed, and the criterion is also used to judge the appropriateness of the model. This reasoning, exhibited in the gas consumption and temperature problem, is directly exemplified by P7: "...we positioned the line so it touched the maximum amount of points".

A3. *Attention to irregularity*. To describe a tendency or when judging the intensity of the correlation, points that deviate from a possible regularity or that are misaligned are noted and used as an argument. For example, when describing the tendency in the data presented in the scatterplot (height and arm measures problem), P4 responded "No [tendency is noted or present], there are only 4 points aligned".

A4. *Software references*. When describing a tendency in the data or justifying a proposal for the line of best fit, actions with the software are mentioned but no response to the actual question is given; as an example of such reasoning, P1 responded (gas consumption and temperature problem) "...we draw the line with the pointer until adjusting it".

A5. *Idiosyncratic*. Answers are given using terms that do not correspond to the common (statistical) usage; most likely, students assign a personal meaning that is not possible to deduce from their written statements. P18 exemplifies this rationale when describe their expectation about how gas consumption varies with the temperature by saying "it all should depend of the weather".

B1. *Describe the tendency*. Students formulate expressions that indicate if the tendency is either positive or negative. Such expressions can be widely general like "goes down/goes up", or much more specific "as long as  $X$  increments,  $Y$  diminishes". For example, when describing the type of tendency in both problems, P3 and P16 mentioned, respectively, "yes, the points are rising and forming a straight line", and "at a higher temperature the less [gas] consumption, and the lower the temperature the higher [gas] consumption".

B2. *Exclusive reference to the line*. The criterion consists of identifying the staggering of the points around a straight line but without describing its' direction; e.g., when describing the tendency in the data in the gas consumption problem, students like P20 provide answers like "yes, [the points group into] in a straight line".

B3. *Through the middle of the points*. This method consists of proposing a line that goes through the middle of the data set in the scatterplot; in some cases, it refers to getting an equal number of points on each side of the line (one half above and the other one under). As an example of such strategy, P5 justified their proposal of the best fit line in the height and arm measures problem by saying "we placed it in the middle of the points to adjust it the most".

B4. *Closeness*. The best fit line is the one considered as the closest to all points, in which “closeness” implies minimizing the sum of the residuals. This type of responses arises when students observe how the least square method is about using the software. An example of such thinking is provided by P1 in the height and arm measure problem: “[we placed the line]so that all the points are the closest to it”, or by P9 when comparing and analyzing their own proposal of the best fit line: “[in our case] the points are farer to the line, so the squares get bigger”.

C1. *Software use*. These responses only provide results or values taken from the software without adding comments or interpretations about them; for example, when P3 is trying to describe the intensity of the correlation in the height and arm measures problem, they just provide the value for  $r$ : “0.883844”.

## Conclusions and discussion

We consider codes A1 and A2 as central when designing a teaching strategy. The term “illusion of linearity” has been adopted from van Doreen, de Boek, Depaepe, Janssens & Verschaffel (2003) who rely on Freudenthal and define it as “the seduction to deal with each numerical relation as though it were linear”; the authors mention that such reasoning has been found in probability tasks as well as in arithmetic and algebraic domains. Casey (2014) pointed out that “many students required that their line [of best fit] go through the origin [...], they had a preconceived notion that all lines start there”, a similar reasoning we understand as a geometric form of the linearity illusion; however, it should be noted that both reasonings are not fully equivalent but mathematically related to each other. In our previous study (Medina et al., 2016), about 80% of the responses were coded as A1 while in the current one this percentage diminished to 40% (Table 1). We interpret that the often-inadequate exploitation of such resource goes beyond the overvaluation it receives in most elementary educational curricula (e.g., consider Darwin’s famous statement: “I have no faith in anything short of actual measurement and the rule of three”; such reasoning was quite common before Galton and others’ statistical contributions).

<i>Code</i>	<i>A1</i>	<i>B1</i>	<i>Others</i>
Gas consumption problem	8	3	9

**Table 1: Incidence of codes in pairs of students given to the prediction item**

The rationale behind code A2 (incidence in the maximum amount of points) was also found in Casey’s 2014 revision, in which she explains its presence as a consequence of previous learning gained in other mathematical domains such as analytic geometry. Besides addressing its possible causes, it is also convenient to discuss its possible implications. Students’ reasoning seems to partition the data into two parts, cases that rely directly into the linear model (explicit or imaginary) and those that doesn’t; that is, cases that belong or fulfill the model conditions and the ones that don’t. This lends support to the conjecture that at this point, students are still struggling to assume the data as an aggregate but at the most, as an aggregate partitioned in two.

The logic behind code A3 (attention to irregularity) could be expressed as a particular case of the former but focused exclusively on the points “outside” of the model. In doing so, the points that “deviate” from the model are considered as a different class with respect to the others, which may

be interpreted as a form to deal (or exclude) the notion of error involved in the use of statistical-inferential models, or even as expressions of overprivileged technical-deterministic reasoning (which could be addressed by promoting more reflection into the context of the data; e.g., by elucidating possible causes for the “lack of adjustment” of all the points).

As showed in Table 2, codes B1 (describe the tendency) and B2 (exclusive reference to the line) had an increased frequency when dealing with the second problem (final stage of the HLT), and a significant increase was also evident for code A3. The bigger frequency for code B1 might be attributed to students gained experience in this point of the trajectory despite the fact of dealing with a negative correlation; however, this feature might also have provoked that A3 appeared more often because of attending a more disperse data set.

<i>Codes</i>	<i>B1</i>	<i>B2</i>	<i>A3</i>	<i>Others</i>
Gas consumption problem	2	4	1	13
Height and arm problem	5	5	5	5

**Table 2: Incidence of codes in pairs of students when describing the tendency in the data**

As previously mentioned, codes B3 and B4 appeared as criteria of students when attempting to elaborate a linear model of their own (Table 3). Such codes were absent in our 2016 study, which led us to believe that their emergence might be motivated by the incorporation of the software to the instruction sequence. Specifically, adding a movable line and then comparing it against the least squares line seemed to have enable students identify how the former “goes through all of the points”; also, displaying and interpreting the sum of the squares through the software helped to capitalize the idea of the line of the best fit as the one that best approximates all points in the data set.

<i>Codes</i>	<i>B3</i>	<i>B4</i>	<i>Others</i>
Gas consumption problem	2	0	18
Height and arm problem	2	6	8

**Table 3: Incidence of codes in pairs of students when elaborating a line of best fit on their own**

To summarize and conclude this report, codes A1 and A2 are considered patterns that evidence students’ struggle when considering a data set as an aggregate in the context of linear regression and correlation problems. Codes B1 and B2 indicate a progress in students’ conceptions regarding their ability to conceive and identify a general structure subjacent to the data, although with great challenge when it comes to interpret and reconcile the random inferential nature of the model. The emergence of codes B3 and B4 suggest that the use of Fathom might have contributed to improve students’ understanding by helping them to associate the line of best fit to the one that minimizes the sum of errors or deviations between the points and the model. Finally, a major limitation of the HLT is the lack of incidence in promoting reflection upon the reasons of why such correlations might exist (or not); a new version of the HLT and future researches could target such deficiency by addressing students’ reasoning in aspects related to causality and variability.

*The research comes from a multifaceted program designed to provide in-service lower primary school teachers (Grades 1-3; ages 6-9) with the knowledge, skills, confidence, and practical experience required to effectively integrate digital games within the early mathematics curriculum. The article focuses on one of the teachers, employing a single case study approach to document the level of transfer and adoption of the acquired knowledge and skills into actual teaching practice. Findings provide some useful insights into the ways in which the program experiences influenced the teacher's competence in selecting, evaluating, and productively utilizing digital games to enhance learning of key statistical concepts included in the mathematics curriculum.*

*Keywords: Educational games, professional development, TPACK, early statistics education*

## Introduction

The expanding use of data for prediction and decision-making in almost all domains of life makes it a priority for mathematics instruction to help students of all ages develop their statistical reasoning. It is now widely recognized that the foundations for statistical reasoning should be laid in the earliest years of schooling rather than being reserved for secondary school or university studies. Consequently, the development of students' statistical literacy has become an important goal of mathematics education at the early school level internationally. This broadening of the mathematics curriculum to encompass statistical literacy, reasoning, and thinking has put considerable demands on teachers (Hannigan, Gill, & Leavy, 2013). In particular, it has been challenging for teachers to design lessons with engaging contexts and a focus on conceptual aspects of statistics, and to pose critical questions. As the research literature indicates, many teachers tend focus instruction on the procedural aspects of statistics rather than on conceptual understanding (Watson, 2001).

Recognizing the need for fundamental changes to the instructional practices employed in the mathematics classroom to teach statistical concepts, researchers have in recent years been experimenting with new models of teaching that are focused on inquiry-based, technology-enhanced instruction and on statistical problem-solving (e.g., Meletiou-Mavrotheris, & Paparistodemou, 2015). One promising approach lately explored is the potential for digital games to transform statistics instruction. Unlike the numerous studies investigating the instructional use of computer simulations, animations, and dynamic software, there only few published studies on the use of games for teaching statistics, the general thrust of the evidence in the existing literature is positive (Boyle, MacArthur, Connolly, Hailey, Manea, Kärki, & van Rosmalen, 2014). Findings concur with the general educational literature on game-enhanced learning which suggests that when suitably designed, digital educational games have many potential benefits for teaching and learning at all levels, including pre-school and early school years (Manassis, 2014). Most of the conducted

studies report that employing games has a positive effect on students' motivation and learning of statistical concepts (e.g. Gresalfi and Barab, 2011; Boyle et al., 2014). Digital games' greatest strength as a medium, involve their affordances for supporting higher order cognitive, intrapersonal, and interpersonal learning objectives (Clark, Tanner-Smith & Killingsworth 2014). Using games, children can individually or collaboratively engage in exploration of virtual worlds, and in authentic problem solving activities. This supports the development of important competencies essential in modern society such as logical and strategic thinking, planning, multi-tasking, self-monitoring, communication, negotiation, group decision-making, pattern recognition, accuracy, speed of calculation, and data-handling. At the same time, games can promote differentiation of instruction by matching challenges to children's skill level, and by providing immediate feedback to students about the correctness of their strategies and thought processes.

While digital educational games provide a range of potential benefits for mathematics and statistics teaching and learning, not all the games are designed to promote optimal development among children. Most of the available educational games tend to be a drill-and practice and to support mainly procedural fluency rather than high-level thinking. Some exceptional exemplars do exist that can help create constructive, and meaningful learning experiences, but their successful deployment in the early statistic classroom is highly dependent upon the knowledge, attitudes, and experiences of teachers. Implementing game-based instruction can be a challenge for teachers, requiring skills not necessarily addressed in current teacher training practices. Teachers need to be proactive, choosing high quality educational games, supporting and scaffolding pupils, and providing appropriate feedback

Acknowledging the educational potential of games for transforming statistics instruction in the early years, but also the crucial role of teachers in any effort to bring about change and innovation, the current study focused on providing in-service teacher education on the effective utilization of digital games in the lower primary classroom (ages 6-9). An exploratory case study took place within a Cypriot teacher professional development program on the integration of games within the early mathematics curriculum developed based on the notion of Technological Pedagogical Content Knowledge (TPACK) as a conceptual framework (Mishra and Koehler, 2006). It focused on one of the program participants and investigated the development of his TPACK of game-enhanced teaching and learning of statistical concepts included in the early primary mathematics curriculum

## **Methodology**

### **Program Structure, Context and Participants**

The professional development program was attended by six lower primary school level educators (Grades 1-3; ages 6-9), and it was designed to provide them with the knowledge, skills, confidence, and practical experience required to effectively exploit digital games as a tool for fostering young children's motivation and learning of mathematics. Following the TPACK model and action research procedures, the program was designed and carried out in three phases:

- *Phase I – Familiarization with Game-Based Learning:* In Phase I (6 hours duration), teachers were offered a critical introduction into the potential and challenges of using serious games in early mathematics and statistics instruction. They experienced some of the ways in which

purposefully selected games, blended with carefully constructed learning experiences, could help improve children's attitudes towards the subjects, while at the same time advancing their mathematical and statistical thinking and problem solving skills. The unit also familiarized participants with the design principles for constructivist gaming environments (Munoz-Rosario & Widmeyer, 2009), and promoted the development of their skills in properly evaluating and selecting games with pedagogically sound design features.

- *Phase II – Lesson Planning:* In Phase II, teachers' TPACK was enhanced through their engagement in lesson planning. They selected a topic from the national mathematics curriculum for Grades 1-3, and developed a lesson plan and accompanying teaching material aligned with the learning objectives specified in the curriculum, which incorporated the use of digital games. They were instructed to integrate into their lessons educational games that adhered to important principles associated well-designed educational games (Gee, 2007) such as facilitation of an authentic learning experience, active participation, collaboration, and promotion of higher order thinking skills. The lesson plans were shared with the researchers for comments and suggestions, and were revised based upon received feedback.
- *Phase III – Lesson Implementation and Reflection:* Next, the participants implemented the lesson plans in their classroom, with the support of the research team. Once the classroom research was completed, teachers prepared and submitted a reflection paper, where they shared their observations on students' reactions during the lesson, noting what went well and what difficulties they faced and making suggestions for improvement.

Detailed information regarding the implementation of the different Phases of the program and their impact on the whole group of participating teachers can be found in Meletiou-Mavrotheris, Paparistodemou, & Tsouccas (2018). In this article, we focus on Phase III of the program. We draw upon the data collected from the case study teacher and his students to investigate the level of transfer and adoption of TPACK competencies acquired through the training to actual teaching practice. This teacher, who was an expert educator (9 years of teaching experience), was the sole program participant whose teaching intervention focused on concepts related to statistical data analysis. The rest prepared and implemented lesson plans focusing on other areas of the mathematics curriculum.

### **Research Design: Scope and Context of Study**

The teaching intervention took place in a Grade 2 classroom with 18 students, and lasted for 80 minutes (two teaching periods). The class teacher selected a topic from the national mathematics curriculum for Grades 1-3, and developed a lesson plan and accompanying teaching material aligned with the learning objectives specified in the curriculum, which incorporated the use of mobile game apps. The lesson plan targeted the following indicators of achievement included in the curriculum for Grade 2: (i) Collect information and data in the environment and present them in an organized way; (ii) Record, organize and present data in tables and graphical representations (pictogram, bar graph, pie chart); (iii) Represent the same data in multiple ways.

The lesson plan was shared with the researchers for comments and suggestions, and was revised based upon received feedback. Next, the teacher implemented the lesson plan in his classroom, with

the support of the research team, and afterwards prepared a reflection paper where he shared his observations on students' reactions during the teaching intervention, noting what went well and what difficulties he faced and making suggestions for improvement.

Central to the teaching intervention was the game app The Electric Company Prankster Planet, available on Android and iOS platforms as well as online. Prankster Planet is based on the Emmy Award-winning PBS KIDS TV series The Electric Company, and it targets children aged 6-10. It features eight unique quests with math curriculum woven throughout that children have to complete to save Earth from the Reverse-a-ball machines of Prankster character Francine, that are scrambling up all the words on Earth and are causing a lot of confusion. Children complete a series of data collection, representation and analysis challenges in order to shut down all eight machines hidden in the jungles, cities, junkyards, and underground world of Prankster Planet. The app features side-scrolling play and exploration in a 2D platformer world, an avatar creator with many customization options, a rewards system to encourage repeat play, and the option of collaborative play through group activities. The online gaming platform Kahoot! was also used during the lesson.

### **Data collection and analysis procedures**

Although multiple forms of data were collected to document changes in teachers' perceptions and attitudes, and in their TPACK of game-enhanced learning as a result of participating in the teacher professional program, only data collected during Phase III in the case study teacher's class was utilized in this study. Researchers were present in the class, observing closely and videotaping the lesson, keeping field notes, and collecting student work samples. Qualitative data were also obtained from the reflection papers written by the teacher at the end of the lesson.

For the purpose of analysis, we did not use an analytical framework with predetermined categories to assess how the teacher's acquired TPACK impacted his teaching practice, due to the lack of well-established frameworks and methodological insights for studying game-enhanced statistics education in the context of in-service teacher training. What we did instead was to identify, through careful reviewing of the transcripts, reflection paper, and other data collected during the study, recurring themes or patterns in the data. To increase the reliability of the findings, the activities were analyzed and categorized by all three researchers. Inter-rater discrepancies were resolved through discussion.

## **Results**

### **Teaching intervention overview**

The lesson started with the teacher informing the class that the headmistress needed information about students' preferences on afternoon activities, to plan for the next school year. Therefore, she would like each class to collect data on their preferences, organize them, and present them in way that would help her come up with a schedule of activities that would satisfy as many children as possible.

To tackle the task, the class first decided to do a census where each student selected their favorite afternoon activity among five options. Then, they recorded their preferences on a tally table, and counted the total number of students selecting each activity. This was followed by class discussion

on how to best present the survey results to the headmistress. During this discussion, children were introduced to bar graphs, the process of their construction, and the ways in which this graphical representation can help to present and interpret the results of a survey, and make decisions.

Next, children played in pairs the digital game Prankster Planet on their iPads. They were asked to go through all eight increasingly difficult missions of the game. Within each mission, they responded to various questions where they had to interpret a bar chart or a pie-chart, or to construct such graphs, in order to collect as many points as possible (see Figure 1). Throughout the activity, the teacher went around the class and offered personalized assistance to each pair of students. Although children were fully engaged with the game and quickly learned its mechanics (possibly due to their high degree of familiarity with digital games as the vast majority owned a tablet at home), they needed some help from their teacher in understanding the posed questions, which were in English.

**Figure 1: A pair of students interpreting a bar graph in Prankster Planet**

Finally, children completed an exercise adopted from their mathematics textbook. They were presented with a table showing the number of hours of sleep per day of 12 different mammals. First, they worked in pairs to complete a task in Kahoot! where they responded to various questions related to the information included in the table. The task was set up as a contest, where each correct answer gave different points to the pair, depending on their response time. For each question, the right answer appeared on the whiteboard, as well as a bar chart showing the children that answered it correctly, and the score of each pair. After completing the task, the children worked individually to construct a “bar graph” of the data in their notebook (a simple histogram in reality), with each bar corresponding to an interval of hours of sleep (i.e. animals sleeping between 0-5 hours, between 6-10 hours, etc.). Finally, through a second contest, they were again given the opportunity to collect points and to win by interpreting the graph they had just built, and answering various questions (e.g. *How many animals sleep more than 5 hours and less than 16 hours per day?*).

At the end of the lesson, a discussion took place, where the teacher highlighted the main statistical concepts introduced during the lesson. Children were encouraged to express their opinion about the format of the lesson and whether they would like to again use similar digital games in class.

## Reflection on the teaching intervention

The case study teacher's past exposure to mathematics education games was limited to drill-and-practice, which he tended to use in class for motivational purposes, and/or for students to practice already acquired skills. However, his participation in the program helped him realize digital games' true potential for supporting learning in educationally powerful ways. Through familiarization with the design principles for constructivist gaming environments and experimentation with a range of game apps, he gained better understanding of how to implement game-based mathematics and statistics instruction in the early years. He also improved his ability to assess the educative power of different games, to properly identify their advantages and disadvantages.

Observation of the teaching intervention, and the quality of the lesson plan and tasks prepared by the teacher, indicated that the specific educator acquired the necessary skills and competencies for teaching this topic and similar statistical topics using tablets and game apps like Prankster Planet and Kahoot! He selected appropriate game apps and then exploited them to organize teaching in a constructive, learner-centered way, so that his young students would have the opportunity to work together in constructing statistical concepts and processes. Specifically, in several activities, children collaborated to build joint understanding of the new concepts they had just encountered. For example, to respond to some of the Prankster Planet questions, students worked together to understand and interpret pie-charts, which had never been mentioned in class before.

As expected, the game-based nature of the lesson was well received by students and increased their morale and motivation. In the end of intervention discussion, children expressed their enthusiasm about the games they engaged with during the lesson, *"because they gave [them] the chance to play and learn at the same time"*. Although expressing a preference for *"the game where [they] had to prevent the Lady from changing the letters"* (i.e. Prankster Planet) which they found to be *"more adventurous"*, they also liked the game on Kahoot! because it was set up as a contest. The children stressed that they would love all their lessons to have a similar format since games enable them *"to learn more things about mathematics and to have a joyful time in class"*.

In the reflection paper he wrote after the teaching intervention's completion, the teacher also noted that he was very impressed by the fact that the lesson ended up being so successful:

Teacher: The children got excited with the games, were constantly active, there was rivalry between the teams, but also collaboration within each team, and this had a positive impact on children's motivation, but also on the attainment of the instructional objectives. Even the supposedly "weakest" students had strong interest and active participation during the lesson and gave several thoughtful answers, with no trace of fear of making a mistake. These are qualities I do not usually experience in lessons where I do not use digital games.

According to the teacher, the use of the games led to an effortless involvement of all children, and contributed substantially to the achievement of the learning objectives, but also to ensuring fruitful cooperation among learners and collaborative construction of knowledge in a creative and enjoyable way. Lastly, use of technology worked exactly as he had anticipated, providing the opportunity to introduce in the classroom activities with added value, that could not otherwise be implemented.

While the classroom experimentation further strengthened the teacher's belief that appropriate use of game apps can help create motivational and more conducive to learning environments, it also helped him to build more realistic expectations about what games' instructional integration might entail in practice. He recognized that games are not a panacea, and that their incorporation into the curriculum does not guarantee improved learning. He mentioned various challenges and drawbacks to digital games' incorporation in the mathematics classroom, including time constraints, difficulties in locating high-level games, the risk of the learning objectives being neglected for the sake of playfulness, and language issues for non-native English speakers:

Teacher: The fact that Prankster Planet is in English, prohibited its optimal use. While students played, I had to constantly move around to translate things to them.

The teacher stressed the key role of educators not only in choosing appropriate digital games with the goals of gameplay being closely aligned with instructional objectives, but also in "*coordinating classroom activities appropriately so as to keep children focused on the achievement of the learning objectives*", and in facilitating learning by providing continued support and scaffolding. He pointed out that games should not dominate class time, but should be used as part of carefully planned learning experiences, and explained how, in his teaching experimentation, the use of alternative pre-game and post-game instructional activities led to a fuller learning experience. His comments concur with the literature, which indicates that digital games are more effective when acting as adjuncts to more traditional teaching methods rather than as stand-alone applications (Gee, 2007).

## Discussion

This case study has several limitations, emerging primarily from its exploratory nature, which constrain the interpretation of the research results. A serious drawback is the limited generalizability of the research findings. The qualitative methodology used to research the case, the small scale of the study, and its limited geographical nature, means that generalizations to cases that are not very similar should be done cautiously as the specific classroom investigated might not be representative of all pre-service teacher classrooms. Despite, however, the tentative and non-generalizable nature of its findings, the conducted research contributes some useful insights into the accumulating body of literature on game-enhanced statistics teaching and learning.

In accord with the research literature (e.g. Niess et al., 2009), our research has illustrated the usefulness of the TPACK framework as a means of both studying and facilitating teachers' professional growth. Although there was no pre-post test assessment to formally track changes teachers' TPACK, there are strong indications in the collected data that the training was quite successful in helping the case study teacher (as well as the other program participants) move beyond his restricted views of digital games as educational tools (for more details see Meletiou-Mavrotheris et al., 2018). Secondly, that it helped to convey to him technological and pedagogical knowledge regarding the teaching of specific mathematical and statistical concepts with games. Thirdly, that it improved the teacher's confidence and ability to transfer and adopt the TPACK competencies acquired through their training to actual teaching practice.

There are important implications for the design or revamping of pre-service or in-service teacher training curricula and programs on digital game integration. Insights from the study suggest that

utilizing a conceptually based theoretical framework about the relationship between technology and teaching like TPACK, can enrich teachers' professional development. Findings also indicate that the development of teachers' TPACK necessitates the provision of opportunities for both theoretical and experiential learning of technology-based pedagogical approaches to mathematics education. Concurring with prior research (e.g. Serradó, Meletiou-Mavrotheris, & Paparistodemou, 2014), this study provides evidence that teachers' involvement in professional development activities such as lesson design and classroom experimentation, can support them in developing their teaching competencies with ICT and understanding of TPACK in ways transferable into their own practice.

# The influence of the context of conditional probability problems on probabilistic thinking: A case study with teacher candidates

Beyza Olgun<sup>1</sup> and Mine Isiksal-Bostan<sup>2</sup>

<sup>1</sup>Middle East Technical University, Turkey; [bolgun@metu.edu.tr](mailto:bolgun@metu.edu.tr)

<sup>2</sup>Middle East Technical University, Turkey; [misiksal@metu.edu.tr](mailto:misiksal@metu.edu.tr)

*This study investigates the influence of the context of conditional probability problems on probabilistic thinking processes of mathematics teacher candidates. Data were collected from four mathematics teacher candidates through semi-structured clinical interviews. Teacher candidates were expected to solve and explain three conditional probability problems, which were selected based on specific contexts. The findings revealed that, when the context is related to a social issue such as health or justice, that can be a hindrance to probabilistic thinking. In addition, while solving questions, teacher candidates focused on their beliefs regarding the social issue rather than using logical and numerical reasoning given in the questions. On the other hand, the findings highlighted the importance of the instruction on conditional probability, as the candidates represented a high-level of probabilistic thinking in the case of consecutive events that were frequently used in curricula.*

*Keywords: Probabilistic thinking, the context of a conditional probability problem, mathematics teacher candidates*

## Introduction

As probabilistic thinking involves quantifying uncertainty to arrive at a decision, it has an important role in interpreting uncertain situations in daily life (Amir & Williams, 1999). It helps us better understand whether or not the information gained through our everyday experiences is correct (Metz, 1998). Therefore, probability is recognized as an essential aspect of school mathematics curricula from elementary to undergraduate education (Amir & Williams, 1999). Developing students' skills of probabilistic thinking is one of the main aims of the mathematics curricula in Turkey (MEB, 2018). The development of probabilistic thinking depends on the interactions between "intuition, logical development, and the effects of formal instructions" (Greer, 2001, p. 25). From the educational perspective, the aim is to enhance students' probabilistic thinking from intuitive to more advanced logical and numerical reasoning. However, the instruction of probability concepts in schools may cause discomfort in students' proportional reasoning because probabilistic thinking has a fragile aspect when it intuition is concerned (Fischbein, Nello, & Marino, 1991). This weak aspect may cause students engage in subjective reasoning and to act accordingly or to have some misconceptions. Therefore, while planning their instruction, educators need to consider generating an environment that helps students enhance their conceptual understanding, as well as formalizing their initial intuitive concepts (Greer, 2001).

There are four key constructs regarding probabilistic thinking: sample space, probability of an event, probability comparisons, and conditional probability (Jones, Langrall, Thornton, & Mogill, 1997). Conditional probability is one of the fundamental stochastic ideas that enhance probabilistic thinking throughout the history in Heitele's list (Diaz & Batanero, 2009). It allows individuals to make

appropriate changes in their beliefs concerning random events when new information emerges (Diaz & Batanero, 2009). It also helps individuals understand possible risks and make proper decisions in daily life (Watson, 1995). However, compared to the other three key constructs, it requires more careful thinking (Tarr & Lannin, 2005) because of its interest in the outcomes that are elements of a subset of the sample space (Hogg & Tanis, 1993). Therefore, understanding the conditional probability involves the adjustment of the probability of an event when there is a condition regarding the occurrence of another event (Tarr & Lannin, 2005).

Studies showed that students have various misconceptions regarding conditional probability, such as *the transposed conditional fallacy*, *the fallacy of time axis*, and *the base rate fallacy* (e.g., Diaz & Batanero, 2008; Koehler, 1996). The analysis of these misconceptions reveals the influence of the context of probability problems on students' reasoning. In other words, people can approach the problems of conditional probability in various ways when they fail to use appropriate theories (Tversky & Kahneman, 1982). For example, a Bayesian problem that involves two types of information regarding an event – statistics for a population and its specific part of it – can cause a hindrance to student thinking, which leads to the base rate fallacy (Diaz & Batanero, 2009). Moreover, the probability problems that involve medical issues, such as having cancer and taking a related test can be confusing for students as these problems involve the daily experiences of individuals. Students' ways of thinking can be causal based on the scenario or their motive (Tversky & Kahneman, 1982). On the other hand, in some cases where students are accustomed to school experiences, such as consecutive experiments, they can show high-level probabilistic thinking skills (Jones et al., 1997). For instance, the use of representations, such as 2-way tables in the text of a probability problem, could enhance thinking processes of students as well as their achievement (Olgun & Işıksal, 2018).

In this research study, as a continuation of the research study that investigated the role of representations on prospective teachers' thinking processes in conditional probability (Olgun & Işıksal, 2018), the relationship between the context of the probability problems and probabilistic thinking processes is examined. The initial analysis of the previous study pointed out a probable relationship between the context of probability problems and probabilistic thinking processes. Thus, the research question of the present study was as follows: How does the context of probability problems influences prospective mathematics teachers' probabilistic thinking processes in conditional probability based on the framework developed by Tarr and Jones (1997)?

## Theoretical Background

Students' understanding of probability, their misconceptions, and their development of probabilistic thinking were the areas of focus in the research literature. To improve the instruction of probability, a coherent frame that reveals students' ways of thinking about probabilistic phenomena is needed (Jones et al., 1997). Therefore, Jones and his colleagues (1997) developed the "Framework for Probabilistic Thinking" to meet this need. The framework consists of four key constructs of probability; *sample space*, *probability of an event*, *probability comparisons*, and *conditional probability*. Tarr and Jones (1997) enhanced this framework for conditional probability. The new framework, which is called the *Framework for Assessing Students' Thinking in Conditional Probability (FASTCP)*, includes *independence* as a new construct. Four levels, namely subjective,

transitional, informal quantitative, and numerical are described for each construct of the framework. The following example represents the thinking levels for conditional probability.

There is a cup that contains two red and two blue marbles. Two marbles, one after another, are picked up randomly, without replacement. When students were asked what color marble would be picked given that the first marble is red, based on the FASTCP, the response of “red because it is my favorite color” (Tarr & Jones, 1997, p. 51) would belong to a student in level 1 (subjective). To state it differently, level 1 involves the use of subjective reasoning based on personal traits without considering numerical information. At level 2 (transitional), students begin to use quantitative information, but still, their conditional reasoning is not complete, so students can respond by making such utterances as follows “the probability that blue will be drawn is still the same” (Tarr & Jones, 1997, p. 52). In other words, students misuse numerical information and act with representative heuristics at the transitional level of probabilistic thinking. Moreover, they may still revert to subjective judgments. At level 3 (informal quantitative), students recognize the role of quantitative information for conditional probability as well as monitor the composition of the sample space. Level 3 students can respond by stating that there is one red marble instead of four but still they may also show representative acts or assign incorrect numerical probabilities (Tarr & Jones, 1997). At level 4, as students assign numerical probabilities spontaneously and explain the conditions when the events are related, the response could be that the chance of red is one out of three and the chance of blue is two out of three (Tarr & Jones, 1997). In other words, the numerical level involves the awareness of the composition of the sample space and its essential role in determining conditional probability.

Some studies (e.g., Diaz & Batanero, 2008) showed that students whose probabilistic thinking are at the numerical level might revert subjective reasoning and show biases while performing on probability problems. The importance of the role of intuition in probabilistic thinking and the fragility of probabilistic reasoning in some situations make us inquire what factors influence students' probabilistic thinking. The investigation of students' biases represents the influence of the context of the problems in conditional probability on student thinking. Some studies claim that conditional probability problems, which involve cause and effect relations, confuse students' judgments about the probabilistic phenomena (Biaz & Batanero, 2009). Students rely on causal data that include their perceptions formed via daily life experiences rather than diagnostic data (Diaz & Batanero, 2009). In the case of the Bayesian problems, which involve the issue of base rates, students may ignore the information related to the base rate and tend to rely on the specific information given in the problems (Koehler, 1996). When the context of conditional probability problems involves social contexts, such as justice or health issues, students' beliefs based on personal experiences may get ahead of their logical reasoning. Some studies (e.g., Corter & Zahner, 2007; Watson, 1995) suggest that the use of representations can facilitate students' problem-solving processes and lead them to use logical-numerical reasoning. However, students may still resort to erroneous judgments for problems based on certain contexts rather than using representations as a model (Olgun & Işıksal, 2018). Based on the literature it could be deduced that there are limited studies that have focused on the context of probability problems in the case of conditional probability while modelling and representations have been investigated by many researchers (Chaput, Girard & Henry, 2011). These issues necessitate a study investigating how different contexts of probability problems influence probabilistic thinking

processes. Such a study can reveal some information about the instruction of conditional probability as well as students' thinking processes. Therefore, the current study will investigate the influence of different contexts in conditional probability problems on probabilistic thinking processes of teacher candidates based on the FASTCP.

## Methodology

Gaining a deep understanding of participants' thinking processes was the main objective of the present study, in which semi-structured clinical interviews were held with the participants, who were selected by means of the convenient sampling method. The participants were students, who were in their 4th semester of teacher education program and who had taken "MATH 112 Discrete Mathematics" and "STAT 201-202 Introduction to Probability and Statistics I-II" courses. These students were informed about the research study. The interviews were conducted with the volunteer students. Four (two male and two female second-year students between the age of 20-22 years) students enrolled in the mathematics teacher education program of one of the largest public universities in Turkey constituted the participants of the study.

In the interviews, the participants were asked to perform on three specific conditional probability problems (see Figure 1), which were selected from the Conditional Probability Reasoning Test (CPR) developed by Diaz and Batanero (2009). Each problem was determined according to its specific context. Problem 1 was related to a consecutive experiment involving computing conditional probability and dependence of the events. Problems 2 and 3 included the social context of justice and health issues, respectively. In problem 2, which is a Bayesian problem, two types of information were given: the frequency of the base rate and specific information about the case. Problem 3 was related to a causal issue including the application of a medical test and whether or not there was an illness.

**Problem 1:** (Falk 1986). Two black and two white marbles are put in an urn. We pick a marble from the urn. Then, without putting it back into the urn, we pick a second marble at random.

If the second marble is white, what is the probability that the first marble is white?  $P(W_1 | W_2)$

- i.  $1/3$
- ii. Cannot be computed
- iii.  $1/6$
- iv.  $1/2$

**Problem 2:** (Tversky & Kahneman 1982a). A witness sees a crime involving a taxi in a city. The witness says that the taxi is blue. It is known from previous research that witnesses are correct 80% of the time when making such statements. The police also know that 15% of the taxis in the city are blue, the other 85% being green. What is the probability that a blue taxi was involved in the crime?

- a.  $\frac{80}{100}$
- b.  $\frac{15}{100}$
- c.  $\frac{15 \times 80}{100 \times 100}$
- d.  $\frac{15 \times 80}{85 \times 20 + 15 \times 80}$

**Problem 3:** (Pollatsek, et al. 1987). A cancer test is administered to all the residents in a large city. A positive result is indicative of cancer and a negative result of no cancer. Which of the following results is more likely or are they all equally likely?

- a. A person has in fact cancer supposed that he got a positive result.
- b. To have a positive test supposed that the person has cancer.
- c. The two events are equally likely.

**Figure 1: The problems, adapted from "University Students' Knowledge and Biases in Conditional Probability Reasoning", by Diaz and Batanero (2009, pp. 157–158)**

The participants were asked to submit their solutions both in written form and verbally, and the first author asked related questions to understand their in-depth thinking processes. Each interview lasted 90 to 120 minutes and was videotaped and transcribed. The demographic information and the consent of the participants were obtained in advance. In the data analysis process, students' probabilistic thinking processes were explored based on the FASTCP for each problem. Two researchers performed open coding. After the codes were determined individually, the inter-rater agreement was

calculated to be 90%. Different ideas were discussed until a consensus was reached. General codes were identified based on their match with the respective thinking levels from the FASTCP. For instance, the general codes of "assigning numerical probabilities spontaneously and accurately" and "using and explaining logical-numerical reasoning" were matched with level 4; the general code of "reverting to subjective reasoning even though recognizing numerical information" was matched with level 2. Expert opinion was also obtained on the appropriateness of matching the general codes with the thinking levels.

## Findings

The analysis of the data showed that the context of the problem had an apparent influence on probability thinking processes of the mathematics teacher candidates. It was observed that when the conditional problem includes a social context, which was, in this case, a health issue or justice for a crime, the participants focused on their beliefs based on their daily life experiences and answered the question accordingly. In other words, most of the time, they resorted to subjective reasoning rather than to logical and numerical reasoning. On the other hand, they presented high-level probabilistic thinking in consecutive experiments.

In problem 1, all participants represented the skills of the numerical level of probabilistic thinking. All participants easily recognized the condition for the consecutive experiment. They were aware of the composition of the sample space, which plays an essential part in determining the conditional probability, and applied numerical probabilities with relative ease when the other situations are considered. They could state the necessary conditions whether or not two events were related. They used numerical reasoning while comparing the probabilities of the events for each trail in non-replacement situations. In the following example, it can be seen that the participant executed the required conditions for conditional probability and assigned precise values for the desired events.

Student C: The probability that the first marble is white if the second marble is white... First I will find the probability that the second marble is white. These are WW (white and white) or BW (black and white). For the situation of WW, the probability is  $\frac{1}{2} \times \frac{1}{3} = \frac{1}{6}$ . For the case of BW, the probability is  $\frac{1}{2} \times \frac{2}{3} = \frac{1}{3}$ . Then  $\frac{1}{6} + \frac{1}{3} = \frac{1}{2}$  is the probability that the second marble is white. Here, the probability that the first marble is also white is  $\frac{1}{6}$ . Then, as like before I will calculate the proportion of  $\frac{1/6}{1/2}$ . It is  $\frac{1}{3}$ .

In problem 2, only one participant displayed the skills of numerical level thinking. The other participants displayed the transitional level of thinking. They presented acts of representativeness as a confounding effect when they made decisions and ignored Bayesian reasoning in their solutions. They confused the situation of "the probability of the involvement of a blue taxi in the crime" with "the chance of finding the taxi that was involved in the crime if it is blue". Therefore, they were confused because the possibility of the taxi involved in the crime being blue should be higher as there was a witness when their numerical calculations said the opposite. Another participant also had the misconception of the base rate fallacy. He ignored the specific information regarding the witness and only focused on the frequency of blue taxis as can be seen in the following example.

Student A: Is it not an easier thing for us to have 15% blue? Obviously, the thing that blue taxis are 15% of the taxis in the city increase the possibility to find the taxi that was involved in the crime because the less the rate, the more likely it is to find. ... The possibility of telling the truth is 80%. Then the possibility of being blue is 15% but as I said it is a 15% chance of blue from all taxis. For example, here it multiplies  $80/100$  with  $15/100$  but because I know that 15% of the taxis are blue if I search within this 15%, the possibility of finding will be high. ... I will say that the possibility of finding the taxi that was involved in the crime is one in fifteen...

In problem 3, all participants acted in the transitional level of thinking. They misused numbers in determining probabilities. For example, when the sample space contained two outcomes as positive and negative results, they assumed that these outcomes are equally likely. Students did not use any representation for the information in the problem to facilitate their solutions. Their judgment about the conditional probability reverted to subjective reasoning as can be seen in the following episode:

Student A: In the case of a positive result when the person has cancer, in the case of having cancer when the result of the test was positive... I'm not a person who trusts in tests that related to health, so I think that the probability of having a positive result in the state of being ill will be lower.

Interviewer: It was a subjective judgment; do not you think?

Student A: Yes, but the question is also very subjective

Interviewer: Can we make a numerical comparison?

Student A: If I have this disease, the possibility of my being patient according to the test result %50 likely. I assume I have cancer then there are two possibilities that this device will show me as plus or negative. If not, it is the same for the other also... So, as I said, I still think that the possibility of having a positive test result supposed that the person has cancer will be higher than the probability of the person has in fact cancer supposed that the person has cancer.

## Discussion

The findings of the present study revealed the fragile aspect of probabilistic thinking. Teacher candidates' actions varied depending on the context of conditional probability problems. Their intuition, which is one of the main components of probabilistic thinking (Greer, 2001), came into prominence when the context was related to a social issue. On the other hand, they showed high-level probabilistic thinking in consecutive experiments. While they represented all the outcomes via listing or creating a tree diagram for consecutive experiments, they did not use any representation for the other two problems. Therefore, they could not explain their reasoning within logical boundaries based on data representation for the problems associated with social issues. For instance, they could not express the need for the accuracy of the cancer test to solve problem 3. The main reason for this difference might be the standing of the problems related to consecutive experiments in school curricula and the instruction of probability. Consecutive experiments have been frequently used in textbooks as well as in regular instructions. Therefore, teacher candidates may have the appropriate

approach in such scopes. Thus, they may directly focus on logical reasoning and numerical probabilities without resorting to their intuition. On the other hand, in a social context, they resort to subjective reasoning or ignore the importance of the condition.

The frequentist approach that recommends a sequence, which starting with the introduction of data followed by probability through datasets (Chaput et al., 2011), has been implemented in the Turkish school curricula since 2009. Therefore, our participants' initial acquaintance with probability was by means of the old approach, which starts with probability and introduces data environment through chance situations. Thus, the introduction of the conditional probability might have been difficult in adopting probability teaching based on data in high school years. Advanced mathematics courses in undergraduate studies have also been criticized for their instructional methods and the degree to which the required conceptual change regarding the related content is created (CBMS, 2011). These issues highlight the essential role of the instruction of probability. Teachers should enhance students' probabilistic thinking regardless of the context. Therefore, teachers should include both consecutive experiments and probability problems with different contexts in their instruction of conditional probability, rather than continue using similar contexts. Students should adopt logical and numerical reasoning in different contexts, which are used for consecutive events. They should focus on the constructs of probability problems, which help to form conditional probabilistic reasoning, rather than on contextual issues. These suggestions point out adopting a frequentist and problem-solving approach in the context of real data for the instruction of probability (Shaughnessy, 2003).

The current study is limited to the contexts of consecutive experiments and social issues of justice and health. Further studies should be conducted for the comparison of different contexts of probability problems to gain an in-depth understanding of the influence of the context on probabilistic thinking. Moreover, the investigation of how experts use logical and numerical reasoning in different contexts might provide significant insight into the instruction of conditional probability.

# In-service teachers' design, teaching and reflection on probability tasks

Efi Paparistodemou<sup>1</sup> and Maria Meletiou-Mavrotheris<sup>2</sup>

<sup>1</sup> Cyprus Pedagogical Institute, Cyprus, e.paparistodemou@cytanet.com.cy

<sup>2</sup> European University of Cyprus, Cyprus, m.mavrotheris@euc.ac.cy

*The development of students' stochastic literacy has become an overarching goal of statistics education internationally. In particular, teachers design lessons with engaging contexts, focus on conceptual understanding (Watson, 2001) and pose critical questions. The present research focuses on the development of early childhood teachers' thinking on designing and teaching probability tasks. Five early childhood in-service teachers participated in this research, which was organized around three stages of teaching: lesson design, classroom implementation and reflection. The study provides some useful insights into the varying levels of attention that teachers paid during their teaching and into the different types of instructional material they used.*

*Keywords: Statistics education, teacher education, early childhood, tasks, randomness.*

## Background of the study

Statistics education research suggests that enhancing teachers' subject matter knowledge about uncertainty and statistical inference must be given high priority. Building teachers' knowledge of pedagogical structures and tools by itself is not sufficient. Deep understanding of probability is also needed for identifying student errors and implementing effective teaching practices (e.g., Paparistodemou, Potari, & Pitta, 2006).

Consequently, statistics education researchers have, in recent years, engaged in professional development efforts aimed at facilitating the development of both subject matter knowledge and pedagogical content knowledge of teachers (e.g., Groth, Kent, & Hitch, 2015; Leavy, 2010; Serradó, Meletiou-Mavrotheris, & Paparistodemou, 2014). The importance of introducing probability tasks in the early mathematics classroom is related to the idea of constructing stochastic knowledge based on children's intuitions. Currently, probability and statistics have an important role to play in everyone's daily life, and particularly in children's lives where most of the games they engage with include the idea of chance. Research on learning stochastics (Paparistodemou & Noss, 2004) has shown that young children use spatial representations for expressing stochastic ideas. Research (Paparistodemou & Noss, 2004; Pratt, 2000) also shows that the design of activities targeting children aged 4-8, is critical for them to be able to express their probabilistic ideas. For analysing the complexity of teaching mathematics, Potari and Jaworski (2002) used the teaching triad (management of learning, mathematical challenge and sensitivity to students) as an analytical device and as a reflective agent for teaching development by teachers. Management of learning describes the teacher's role in the constitution of the classroom-learning environment by the teachers and students, for example planning of tasks and activity. Mathematical challenge describes the challenges offered to students to engender mathematical thinking and activity and sensitivity to students describes the teacher's knowledge of students and attention to their needs. The present research focuses on teachers' planning, teaching and reflection on young children's (4 to 6 years-old) stochastic activities. The work is part of a previous work (Paparistodemou & Meletiou, 2018) and it concentrates on

teachers' attention on the activity in terms of the mathematical challenge it offers and the development of children's stochastic ideas.

## **Methodology**

### **Participants and context**

Five early childhood teachers (all females) participated in this research, which was organized in three stages: Stage 1 – Lesson Planning, Stage 2 – Lesson Implementation, and Stage 3 – Reflection. In Stage 1, the teachers were engaged in lesson planning. They selected a topic from the national mathematics curriculum on probability and statistics and developed a lesson plan and accompanying teaching material aligned with the learning objectives specified in the curriculum. The lesson plans were shared with the researchers for comments and suggestions, and were revised based upon received feedback. In Stage 2, the teachers implemented the lesson plans in their classroom, with the support of the researchers. Once the classroom implementation was completed, in Stage 3, teachers were interviewed and prepared and submitted a reflection paper, in which they shared their observations on students' reactions during the lesson, noting what went well and what difficulties they faced and making suggestions for improvement.

### **Data collection**

Multiple forms of data were collected: (1) Observations and artifacts collected during Stage 1: Early childhood teachers' submitted work (students' entry slips-student's responses on pre-knowledge tasks, lesson plans, etc.), researchers' observations and field notes; (2) Observations and artifacts collected during Stage 2: Each early childhood teacher intervention that took place lasted for 80 minutes (two teaching periods). Researchers were present, observing closely and videotaping the lesson, keeping field notes, and collecting samples of student work; (3) Individual interviews and reflection reports during Stage 3: Upon completion of Stage 2, the researchers conducted semi-structured interviews with each of the teachers. Qualitative data were also obtained from the reflection papers prepared by the teachers.

For the purpose of analysis, we did not use an analytical framework with predetermined categories to assess how teachers' perceptions evolved. Our coding was open and we tried to recognize mathematical challenges (Potari & Jaworsky, 2002). We identified, through careful reviewing of the transcripts, reports, and other data collected during the study, recurring themes or patterns in the data. To increase the reliability of the findings, the activities were analyzed and categorized by the researchers. Inter-rater discrepancies were resolved through discussion.

### **Designing, teaching and reflecting on probability tasks**

Findings, concerning the study research question on what early childhood teachers attend to when designing, implementing and reflecting on probability tasks, will be discussed with regards to one of the three elements of the teaching triad (Potari & Jaworski, 2002): mathematical challenge, which we call here "stochastical challenge". The learning objectives included in all lesson plans refer to stochastical challenges like the probabilistic concepts of certain, impossible and probable events. Moreover, the lesson plans included activities that involved children in authentic statistical inquiry. The activities included in their lesson plans indicated that they tended not to recognize the concept of

randomness, as it appeared difficult for them to see the stochastic idea underlying tasks (the context). In presenting the main insights from our study, we focus to the *existence of randomness*.

### **The stochastic challenge of making predictions**

In Alice's case, the aim of the lesson plan she designed was for "children to make predictions based on impossible, possible and certain events". She decided to use the context of children making hats for a party:

Alice: You know, children need an everyday scenario... I decided to ask them to make hats with dots. The dots will be blue and/or red... they [the children] will select a spinner, make a prediction as to whether it would be possible for the hat to have blue dots or not, mark it on their board and then make their hat...

Researcher: So, will they use their spinners?

Alice: If they like to...yes. I know that some students will know beforehand...

The other activities included in Alice's lesson plan also indicated lack of attention to the concept of randomness. Alice was focusing only on children making decisions on what might have happened and what not. We had a discussion with Alice to find out why she did not 'allow' children to spin the spinners. She referred to management issues, but after we pointed out the importance of children experiencing randomness, decided for children to spin their spinners. Figure 1 shows how Alice organized her classroom based on the above task.

**Figure 1: Material used in Alice's task**

### **The stochastic challenge of controlling the uncontrolled**

In Sally's case we recognized an awareness of the concept of randomness. Sally was very specific in her two aims for the lesson, which were the following: "Children should be in a position to select the appropriate sample spaces for certain, impossible and fair events", and "Children should experience the concept of randomness". At the beginning of Sally's lesson, children selected their favorite flavor of ice cream. They had this selection stacked on their chair and were given a "fair" spinner with three flavors. They worked in pairs, with one child spinning the spinner and the other one comparing the flavor that had come up in the spinner with his/her favorite flavor (see Figure 2).

**Figure 2: Children playing with spinner in Sally's task**

It was good to see Sally letting the children experience randomness. Another activity she planned and implemented was to show children different spinners, which had different sample spaces (for example, whole brown (as a chocolate flavor), whole red (as a strawberry flavor), whole white (vanilla flavor),  $\frac{1}{4}$  brown- $\frac{3}{8}$  red- $\frac{3}{8}$  white etc.). Children were asked questions such as: “Which spinner should you use in order to get your favorite flavor? Why? If I spin this spinner will I get strawberry? Why or why not?”.

Sally's case is interesting from the point of view that although we recognised from her lesson plan a stochastic challenge awareness, we can see from her teaching that she put a lot of effort in understanding the probability concept and the presence of randomness in her activities. On this point, in her interview she stated:

Researcher: What did you want children to learn?

Sally: Certain, Possible, Different sample spaces... Well, the activity went well. It was not difficult for them... and I think children built a good understanding of the idea of randomness [...] you know, I spent a lot of time to design the lesson... finding the scenario, making the materials... but the “key” was for me to understand... you know... to feel confident that I know... this subject [probability] seems easy but it is not so easy to teach... you need to know.

Researcher: What was it that you needed to know?

Sally: There were many times that in order to continue teaching I had to grasp from their predictions, continue with having the experience and then find a way let's say... giving them [to the children] a chance to “control” this “uncontrolled idea” [randomness]... For example, Dani was sure that he would get brown in a fair spinner... that was not the case... At that point I had to be able to give him an experience of randomness and also help him build his new prediction...

Sally seemed able to recognize some critical incidents in her lessons and to reflect on them. She paid particular attention to the provision of opportunities for children to experience randomness, something that was critical in building on children's intuitions.

Similarly, Alice reflected on her lesson: “I spent hours trying to find the scenario, making the materials and I felt that everything was ready... In this lesson that was not the case... I had also to be able during my teaching to find ways to help children adjust their predictions, making questions and giving the right spinner...”.

In the above paragraphs we present two cases of the five we observed, as these can be also an example of the other two that are missing. Among the five cases of teachers in our study, there was one teacher who did not recognize at all the importance of randomness in her probabilistic activities. Katie expressed her thoughts as follows: “You know, I feel that the lesson did not go so well mainly because I posed too many closed questions and I didn’t feel confident when I got the ‘wrong’ answer... I didn’t realize the need for children to experience randomness until we talked...”. Katie was aware that a deeper understanding of this important probability concept would have helped her to improve her lesson planning and implementation. Besides that, she also reflected on how she should have given the opportunity for children to experience randomness.

## **Discussion and conclusions**

Teachers in our study recognized that they needed to know not only what randomness is and how to deal with this concept, but also how to make it visible in their lesson. They pointed out that successful introduction of the idea of randomness in the early mathematics classroom requires knowledge of how to build upon children’s prior intuitions regarding random phenomena, as well as how to react during the lesson to students’ predictions regarding stochastic events and to the actual outcomes of such events. Teachers discussed on critical incidents they observed (Goodwell, 2006; Hanuscin, 2013). Critical incidents were crucial for jointing reflection between teachers and researchers on concrete classroom situations (Scherer & Steinbring, 2006).

Most of the teachers’ attention during the planning stages was focused on including knowledge of educational goals, where specific concepts appear. This is what Ball and Bass (2000) spoke about what curriculum knowledge is. This type of knowledge may help teachers appropriately sequence the introduction of statistical ideas in a curriculum (Godino, Ortiz, Roa, & Wilhelmi, 2011). The findings show that it was through actually teaching the lesson and after reflection that the knowledge components/challenges became more evident for these early stage teachers. Similar findings were obtained in a previous study conducted by Paparistodemou et al. (2006), which had investigated prospective teachers’ awareness of young children’s stochastic activities. The fact that similar tendencies were observed in both pre-service and in-service teachers might lead us to conclude that awareness is not only a matter of teaching experience, but also of the extent to which teachers engage with the process of noticing and understanding their teaching. In the case of Sally and Alice, we saw some degree of awareness of important concepts like randomness. At some instances, these two teachers indicated some understanding of randomness and of how it relates to other probabilistic concepts, but this was not always the case. We could say that their awareness remains at the level of action (mathematical) and it does not indicate a greater degree of awareness than that of the awareness in discipline (Mason, 1998).

Summing up, this study adds the term of “stochastic challenge” in Potari’s and Jaworski’s (2002) teaching triad and in addition to previous work of Paparistodemou and Meletiou (2018). Furthermore, it shows the kind of experiences that a small group of early childhood teachers’ incorporated into the design, implementation and evaluation of teaching related to stochastics (for more details see also Paparistodemou & Meletiou, 2018). It can be argued that these teachers did build some relations between theory and teaching practice, but that their transition and reflection to more specific stochastic and pedagogical issues appeared to be a difficult endeavor. This calls upon special attention and reflection on behalf of mathematics teacher educators to tackle this problem.

# Connecting context, statistics and software for understanding a randomization test: a case study

Susanne Podworny

Paderborn University, Paderborn, Germany; [podworny@math.upb.de](mailto:podworny@math.upb.de)

*Drawing statistical inference with the help of simulations has gained prominence in statistics education as well as introducing statistical inference with randomization tests. This paper describes some selected results of a case study of preservice primary teachers who attended a short learning trajectory on statistical inference with randomization tests. It will be shown how the participants address the context, statistics and software level when conducting a randomization test with software and how the conscious linking of the three levels can support the learning process and help to understand certain elements of a randomization test.*

*Keywords: Statistical inference, randomization test, simulation.*

## Introduction

Statistical reasoning is a cornerstone on which statistical practice is based. In almost all areas of daily life, data and thus also conclusions drawn from data play an important role. It is impossible to imagine statistical practice without computer-supported evaluations and methods. In many fields, like in industry, medicine, or politics, decisions are increasingly being made on the basis of data. When looking at a newspaper, a television report or an entry on the World Wide Web, interested citizens increasingly come across the keywords “A study has shown ...” or “The effect of X is Y”. However, it is often suggested that the results and interpretations delivered in this way are by no means certain, as is often suggested in the media.

There are two big areas in inferential statistics: parameter estimation and hypothesis testing and there are two kinds of inferences that may be drawn: generalizations beyond a given sample and causation for a given treatment for a given sample. The latter should be an integral part of stochastic education, as called for in the basic article by Wild and Pfannkuch (1999).

Statistics education should really be telling students something every scientist knows, ‘The quest for causes is the most important game in town.’ It should be saying: ‘Here is how statistics helps you in that quest’. (Wild & Pfannkuch, 1999, p. 238)

One statistical method for drawing causal inferences is the randomization method. About ten years ago, Cobb (2007) strongly advocated introducing the logic of inference via randomization tests. A randomization test is a non-parametric method that allows easy access to inferential reasoning via computer-based simulations. Through simulations, nearly no formulas or calculations are needed, and this is one of the main reasons for the easiness of this method. The “core logic of inference” (Cobb, 2007) can be in the center and conclusions are possible even for data from small or non-random samples.

From this perspective, a learning trajectory on inferential reasoning with randomization tests was developed by the author to be implemented in an existing course on statistics and probability for preservice primary school teachers to complete the general statistics education of these preservice

teachers. Eight weeks after the learning trajectory a case study was conducted with participants who conducted a randomization test for a given problem with computer-based simulations. The objective of this paper is to better understand the reasoning process of these learners. Selected findings of this study will be presented in this paper.

## Literature review

Cobb (2007) gave an impetus to rethink the introduction to inference statistics, especially at college level, and to get a new introduction with randomization tests. Some curricula for introductory statistics courses emerged since then (e.g. Rossman, Chance, Cobb, & Holcomb, 2008; Tintle, VanderStoep, & Swanson, 2009; Zieffler & Catalysts for Change, 2013) and some shorter learning trajectories for introducing inferential reasoning were created (e.g. (Budgett, Pfannkuch, Regan, & Wild, 2012; Frischemeier & Biehler, 2014). All these teaching proposals are based on the use of computer-based simulations and focus on the logic of inferential reasoning rather than on calculations. In addition, there are some few empirical studies focusing on special aspects of the process when learners conduct a randomization test.

A common factor of all these learning units is that they use a plan or a scheme to structure the reasoning process. A compilation of elements of these schemes by the author has resulted in nine elements that can be considered central when conducting a randomization test. The first element is the random allocation of experimental units to groups. Explaining this is a core component in understanding the underlying design (Pfannkuch, Budgett, & Arnold, 2015). To find possible explanations for observed differences between two groups of an experiment (Pfannkuch et al., 2015) is the second element. One explanation can be that the treatment is effective, another explanation can be that the observed differences are due to the random allocation of units to the groups. The third element is to pose or reconstruct the research question for the experiment (Wild & Pfannkuch, 1999). Analyzing the observed data and identifying a difference between the two groups is the fourth element (Biehler, Frischemeier, & Podworny, 2015; Rossman et al., 2008). The fifth element is setting up the null model with the null and alternative hypotheses (Biehler et al., 2015). Transferring the null model to a simulation model is the sixth element (Biehler et al., 2015; Lee, Tran, Nickell, & Doerr, 2015). The seventh element is the production of test statistics and the sampling distribution (Lee et al., 2015). The eighth element is to identify the  $p$ -value (Biehler et al., 2015; Rossman et al., 2008). And the last element is drawing possible conclusions (Cobb, 2007). Each of these elements has its own difficulties, but one difficulty across all elements is to combine the levels of context, statistics and software.

In our own research (Biehler et al., 2015), we identified three levels when working on a randomization test: the context level, the statistics level, and the software level. Following up on this, Noll and Kirin (2017) conducted a case study with eight learners who created different models in TinkerPlots for the “dolphin therapy problem” (Noll & Kirin, 2017, p. 219) and analyzed what influenced the learners’ reasoning about models. One of their results was, that “Students did not spend much time discussing attribute labels or what type of devices they wanted to use” (Noll & Kirin, 2017, p. 232). This may be an explanation for the reported result that “the concept of no difference between two groups is difficult to operationalize into a TinkerPlots model” (Noll & Kirin, 2017, p. 235). Naming the (simulated) attributes was identified by Noll and Kirin as an important aspect of the modeling process,

because it can act as a bridge between the context and the tool (Noll & Kirin, 2017, p. 236). But they also state, that they “see this work as in its infancy in that we need more research focused on why students create the models” (Noll & Kirin, 2017, p. 240). They also noted that it is not reasonable to separate the three worlds like they interpreted the work of (Biehler et al., 2015). At this connection between context, statistics and software this paper ties in.

### **The learning trajectory “Inferential reasoning with randomization tests”**

A learning trajectory “Inferential reasoning with randomization tests” for preservice primary school teachers was created in the sense of the design based research paradigm (Cobb, Confrey, diSessa, Lehrer, & Schauble, 2003). The aim of the trajectory was to introduce preservice teachers at university to the logic of inference like in the sense of Cobb (2007) in a short period of time. Some design ideas were adapted from Pfannkuch et al. (2015), who successfully introduced inferential reasoning in a short learning sequence to a similar target group. The learning trajectory was designed for the end of an existing course on elementary statistics at Paderborn University. The existing course consisted of three modules data analysis, combinatorics, and probability and used the software TinkerPlots from the beginning. The new learning trajectory was designed for three 90 minutes sessions.

In the first session the students should get in touch with a first example of a randomization test with a significant  $p$ -value (Rossman et al., 2008) and with the logic of inferential reasoning as a continuation of group comparisons (Makar & Confrey, 2002), which were already discussed in the data analysis module. The second session focused on the performance of a randomization test by the students. First, a hands on simulation with pen and paper was to be carried out and then transferred to a computer-based simulation, like proposed for example by Gould, Davis, Patel, and Esfandiari (2010). In the third session, the nine elements (see literature review) were to be discussed in detail and possible difficulties addressed.

To get insights into the cognitive processes of students conducting a randomization test with TinkerPlots, an interview study was designed as part of the Ph.D. study of the author.

### **Methodology**

The research question for the case study – that is focused on in this paper – is *How do the participants relate the three levels context, statistics and software to each other?*

The problem given to students was an adaption of the “Fish oil and blood pressure task” of Pfannkuch et al. (2015). This task contains real data from a medical experiment with 14 volunteers on the question of whether fish oil supplements have a blood pressure-lowering effect compared to normal oil supplements. The blood pressure of the participants was measured at the beginning and after four weeks and the blood pressure reductions for the two groups were recorded like in Table 1.

Fish oil group	8	12	10	14	2	0	0
“normal oil” group	-6	0	1	2	-3	-4	2

**Table 1: Data on blood pressure reduction after four weeks**

The observed data was visualized on the worksheet for the students like in Figure 1 and accompanied by the statement and the question “The observed data are shown in Figure 1 and show that the blood

pressure reduction in the fish oil group tends to be greater than those in the ‘normal oil’ group”. What can be concluded here?”

**Figure 1: Visualized data on the participants' worksheet**

The interview study took place as a semi structured interview (Mayring, 2016) with a large part of the participants working independently on the task. Questions of the participants were allowed in this phase, and some help could be given by the interviewer. This part was followed by interview questions relating to the individual steps and arguments of the working phase.

A total of six participants working in three pairs took part in the interview study. All of them attended the whole course and the learning trajectory, so this was their educational background. Participation in the study was voluntary, so participants cannot be considered representative of the 236 participants in the whole course. The participants' age ranged between 21 and 25 years, being in the third/fourth semester of University. The interviews took place eight weeks after the course and none of the participants used TinkerPlots in between. The conversations were recorded together with the screen activities and then transferred into a transcript. This transcript included the conversations as well as the other activities, with and without software.

The analysis of the transcripts was carried out by means of interaction analysis (Krummheuer & Naujok, 1999). First, the transcripts were divided into 15 interaction units using methods of linguistic conversation analysis (Egbert & Deppermann, 2012). The next step was to reconstruct the solution process interpretatively with interaction analysis. A detailed turn-by-turn analysis took place here and was discussed with other interpreters. For each of the nine elements (see literature review), the level (context, statistics, software) at which the participants communicated was examined. As a third step, the use of the software in the solution process was examined in detail. Summary and comparative analyses between the pairs formed the fourth step.

## Results

The levels at which the participants communicate regarding the nine elements are described below. Table 2 shows which level the participants address linguistically when they talk about and work on the various elements.

**Table 2: Overview of the levels at which the pairs communicate during the randomization test process**

Table 2 shows a clear pattern. The first two elements are addressed by all three pairs both at the context level and at the statistics level. These are related to the observed data and no reference to the software is necessary. The research question is formulated by the participants at the contextual level. The corresponding interaction units are very short, because this element is obviously clear for all participants. Like the first two elements, the observed data are discussed at the contextual and at the statistical level. As the data had already been evaluated on the worksheet, there was no need to work with the software and therefore no need to talk about it.

The null model element includes the formulation of the null hypothesis and the alternative hypothesis. Communication takes place both at the context level and at the statistics level. However, the null hypothesis formulated by Rebecca and Selina reveals only a small contextual reference. These two formulate “Random group allocation is the cause of observed differences”. Such a formulation is almost arbitrarily applicable to different situations, since a reference to the direct context is not recognizable. The formulation of the other pairs for the null hypothesis are “There is no difference in blood pressure reduction in the effect between both supplements” (Fabia and Laura) and “It does not matter which oil is taken to lower the blood pressure but the results are due to the random allocation” (Mandy and Alisa). Both show a clear connection to the context. Perhaps this explains why Rebecca and Selina do not end up drawing conclusions in context. However, Fabia and Laura do not draw these either, although their null hypothesis is clearly related to the context.

The only element that is addressed by all three pairs on all three levels is the development of the simulation model in TinkerPlots. For this element, all three pairs needed additional help from the interviewer on a technical level, for example how to copy all the observed values into a box of the sampler. The same need of help could be observed for the next two elements for which TinkerPlots had to be used. But, unlike in our earlier research (Biehler et al., 2015), renaming the attributes of the

sampler and of the new groups for the new allocation was a topic for all three pairs. An interesting dialogue for this came about between Rebecca and Selina. This shows that the concept of random allocation developed linguistically by linking the three levels (that was identified as a difficulty by Noll & Kirin (2017)). The sampler built by Rebecca (R) and Selina (S) so far is shown in Figure 2. This sampler is built correctly with all observed blood pressure values in the first box and independently these will be drawn in one of two new groups. TinkerPlots labelled the two stacks in the second device in “a” and “b” automatically.

**Figure 2: Sampler created by Rebecca and Selina**

Selina first renames the first stack in “fish” like in Figure 2, but then retains the letters a and b and the following dialogue arises.

- R: Do we have to call them that, because we actually divide them up in such a way that we can do it later, for example/. So I'm not quite sure, but it could be that we/.
- S: /That's right, we don't really need it.
- R: /put a fish oil person with a normal oil person/.
- S: /You're right/.
- R: /Together. I think a and b is actually quite neutral.
- S: You can actually take a and b, because then that's more. We want to prove now that it has nothing to do with the oil anymore.
- R: Yes, exactly we will say it/.
- S: /So you have to/
- R: We are representatives of the null hypothesis.
- S: Exactly, because then in the one group possibly always both come, a person with fish oil and one with normal oil. It is now only about lowering blood pressure.
- R: Yes, that's exactly what it can be/.
- S: /Yes.
- R: That you have maybe five of them (*points to the fish oil group in the plot in TinkerPlots*) and then (.) the rest of them (*points to the “normal oil” group in the plot*). Well, it can be that way/.
- S: /You're right. (*laughs*) Well, I would spontaneously agree with you. (*laughs*)

In the end, Rebecca and Selina decide not to rename the new groups.

For the next two elements, sampling distribution and *p*-value, none of the three pairs have a conversation at context level. They operate only on the software level and on the statistics level.

Conclusions are correctly formulated at the statistical level by all three pairs, which is a good result for the whole process. The written formulations are as follows:

- Rebecca & Selina: Research hypothesis can be accepted and null hypothesis can be rejected, but with slight uncertainty

- Fabia & Laura: We reject the null hypothesis and accept the research hypothesis at a P-value of 1%.
- Mandy & Alisa: The null hypothesis can be rejected. Blood pressure reduction depends on the type of oil.

However, only Mandy and Alisa apply their conclusion to the treatment carried out. A deeper look at the transcripts shows that the greatest difficulties are with the last element formulating contextual conclusions, and that a statistical formulation seems to be the easiest for the participants.

## Discussion

Like Noll and Kirin (2017), who did not find a separation of the three levels context, statistics, and software to be beneficial, connecting the three levels seems to be extremely useful in the present work. Only when the levels are differentiated a conscious connection between them can take place and thus promote the learning process. An example for a helpful connection can be seen in the selected dialogue between Rebecca and Selina, in which they clarify the meaning of random assignment and its implementation in the software.

For the process of understanding it can be concluded that the dialogue between Rebecca and Selina is one of the most important parts of the conversation, because here the two make it clear that during the simulation (level of software) a random reallocation (level of statistics) of the persons with the blood pressure values (level of context) happens independently (level of statistics) of the oil consumed (level of context). Such discussion would have been desirable for further settings at the software level, as it would enhance understanding by linking the three levels. Unfortunately, very few such dialogues have taken place throughout the case studies. Even though the data are taken from a real scientific experiment, the participants seem to have been given too little opportunity to deal with the context in detail. This would be a better prerequisite for a deeper interpretation of the context.

However, the context caused a confrontation with the data, as reported by Gonzáles (2015), in order to promote understanding of the need of decision-making in situations with uncertainty. The demands of Cobb (2007) were implemented here in a learning trajectory and the learners were successfully introduced to statistical inference.

<sup>2</sup>School of Psychology, Queen's University Belfast, Belfast, UK

*The assessment of probabilistic reasoning skills is important in various context. The aim of this study was to develop an abbreviated, open-ended version of the Probabilistic Reasoning Scale (PRS-B), applying Item Response Theory (IRT). The analyses based on the open-ended version of the 16-item scale suggested the exclusion of seven items that did not perform well in measuring the latent trait. The resulting 9-item scale (PRS-B), which included highly discriminative items, covered a wider range of the measured trait than the original scale and it showed high measurement precision. Concerning validity, the results showed the expected correlations with numerical skills, math anxiety, and statistics achievement. In conclusion, the PRS-B can be is a shorter, open-ended version of the PRS that maintains excellent reliability and validity.*

*Keywords: Assessment, item response theory, short form, probabilistic reasoning, validity.*

## Introduction

The ability to think about uncertain outcomes and to make decisions on the basis of probabilistic information is relevant in many fields (e.g., business, medicine, politics, law, and psychology). However, people often struggle with interpreting probability information (see Chernoff & Sriraman, 2014). In particular, when they solve probability problems, people tend to make some typical mistakes instead of applying formal analytic procedures (see e.g., Gilovich, Griffin, & Kahneman, 2002). These mistakes, including heuristics, biases and misconceptions, make it difficult for people to interpret and critically evaluate probabilistic information, understand data-related arguments, and make reasoned judgments and decisions (e.g. Garfield & del Mas, 2010, Morsanyi et al., 2009; Pratt & Kazak, 2017).

Regarding education in probabilistic reasoning, previous studies demonstrated the difficulty of improving probabilistic reasoning ability or, rather, a resistance to eliminate probabilistic reasoning biases once these had consolidated (for a summary of the literature, see e.g., Gilovich et al., 2002; for adolescents, see Klaczynski, 2004). Nevertheless, training activities that target specific difficulties can reduce some misconceptions (e.g. Fong & Nisbett, 1991). Additionally, in statistic courses, which have been incorporated into a wide range of school and university programs in many countries, students often encounter difficulties and, eventually, many of them fail to pass the exams. Some authors (Konold & Kazak, 2008) pointed out that one of the reasons students have difficulties in learning basic data analysis stem from a lack of basic understanding of probability and in grasping the fundamental ideas of probability.

Given the important role of probabilistic reasoning skills in various contexts, it is important to accurately measure probabilistic reasoning skills, in order to improve these skills. This, in turn, can

lead to other beneficial outcomes, such as better academic achievement. For this reason, recently we developed a new scale, the *Probabilistic Reasoning Scale* – PRS (Primi, Morsanyi, Donati, Galli, & Chiesi, 2017) to measure probabilistic reasoning ability, which can be used to identify people with difficulties in this domain. The PRS was developed with a focus on some typical biases and fallacies that are known to lead to incorrect responses. Indeed, the PRS is a useful tool in educational contexts to identify individuals who could be targeted by specific interventions.

However, the scale has the limitation that the items measure probabilistic reasoning skills most precisely in the lower ability ranges and it is not ideal for the measurement of ability levels around the mean. Additionally, the scale is composed of 16 items and it does not seem appropriate for large, multivariate studies in which many tests and scales need to be administered at the same time. Indeed, with research questions becoming increasingly complex, and involving a growing number of constructs, such as when investigating the role of probabilistic reasoning in decision making (e.g., Schiebener & Brand, 2015) or in risk taking (Donati, Primi, & Chiesi, 2014), shorter scales potentially offer added value.

In sum, the aim of this study was to develop an abbreviated, open-ended version of the PRS. To achieve this goal, we used Item Response Theory (IRT) analyses, which make it possible to select items that offer the most information in measuring the targeted underlying trait, that is, probabilistic reasoning. Specifically, IRT has potential benefits in shortening a scale because it makes it possible to evaluate the amount of information provided by each item of the scale for each trait level on the trait dimension through the Item Information Function (IIF). In other words, if the amount of information is large, the trait level can be estimated with high precision, if the amount of information is small, the trait cannot be accurately estimated. Thus, on the basis of item information, it is possible to select items that convey the higher amount of information along the entire range of the measured trait. Through the selection of items that perform better and assure adequate information along the different levels of the trait, a well-performing shortened scale can be obtained.

Additionally, IRT provides the Test Information Function (TIF), which evaluates the precision of the test at different levels of the measured construct instead of providing a single value (e.g., Cronbach's  $\alpha$ ) for reliability (Embretson & Reise, 2000). More precisely, the TIF provides information on how accurate the test is at estimating a trait along the whole range of trait scores. The more information the test provides at a particular trait level, the smaller the error associated with ability estimation, and the higher the local reliability. Since the TIF is generated by aggregating the IIFs, in general, longer tests will measure an examinee's attribute with greater precision than shorter tests. Nonetheless, in the IRT framework, item selection can be done ensuring that the TIF of the shortened scale maintains an adequate amount of information along the trait continuum, which is similar to the original scale.

Finally, given that a short form of a test should meet the same standards of validity as the full form (Smith, McCarthy, & Anderson, 2000), validity measures were administered to provide evidence that the abbreviated scale still measures probabilistic reasoning adequately. Thus, we expected to replicate the pattern of relationships established for the construct as measured by the long form of the test. In particular, we investigated the relationship between the PRS-B, numerical skills, anxiety and self-confidence related to numbers, and statistics achievement.

## Methods

### Participants

The participants in this study were 316 psychology students (mean age = 20.53; SD = 2.9; 76% female) enrolled in an undergraduate introductory statistics course at the University of Florence in Italy. All students participated on a voluntary basis.

### Materials

*The original Probabilistic Reasoning Scale* (PRS, Primi et al., 2017) consists of 16 multiple-choice questions. In this study, the scale was administered in an open-ended format, which required some minor changes in the wording of the items. The items include questions about simple, conditional and conjunct probabilities, and the numerical data are presented in frequencies or percentages (e.g., “A ball was drawn from a bag containing 10 red, 30 white, 20 blue, and 15 yellow balls. What is the probability that it is neither red nor blue?”).

*The Mathematics Prerequisites for Psychometrics* (MPP; Galli, Chiesi, & Primi, 2011) was developed with the aim of measuring the mathematics skills needed by students enrolling in introductory statistics courses. The test consists of 30 problems, and it has a multiple choice format (one correct out of four alternatives). A single composite score, based on the sum of correct responses, was calculated. In the present sample, Cronbach’s  $\alpha$  was .74. We used this measure as an estimate of students’ math knowledge.

The *Abbreviated Math Anxiety Scale* (AMAS; Hopko, Mahadevan, Bare, & Hunt, 2003; Italian version: Primi, Busdraghi, Tomasetto, Morsanyi, & Chiesi, 2014) measures math anxiety experienced by students in learning and test situations. Participants have to respond on the basis of how anxious they would feel during the events specified (for example, “Listening to another student explain a math formula”). High scores on the scale indicate high math anxiety. A single composite score was obtained, based on participants’ ratings of each statement. In the present sample, Cronbach’s  $\alpha$  was .84.

The *Subjective Numeracy Scale* (Fagerlin et al., 2007) is a subjective measure (i.e., self-assessment) of quantitative ability. An example item is “How good are you at working with fractions?” The items have to be rated on a 6-point Likert scale. A single composite score was computed based on participants’ ratings of each item. Coefficient  $\alpha$  in the current sample was .78.

*Measure of statistics achievement.* As a measure of achievement, we used the final examination grade. The exam consisted of a written task that included three problems to be solved by a paper-and-pencil procedure without the support of a statistics computer package, 5 multiple-choice and 2 open-ended questions (e.g., describe the properties of a normal distribution) and 1 output of data analyses conducted with *R-Commander* to interpret. For the problems, students were given a data matrix (3-4 variables, 10-12 cases) and they had to compute descriptive indices, draw graphs, and choose and apply appropriate statistical tests (identifying the null and the alternative hypotheses, finding the critical value, calculating the value of the test, and making a decision regarding statistical significance). Grades range from 0-30. From 0 to 17 the grade is considered insufficient based on the

Italian University Grading System. Thus, only students who obtain 18 or higher grades pass the examination.

### Procedure

Participants completed the measures individually in a self-administered format in the classroom. Each task was briefly introduced, and instructions for completion were given. The answers were collected in a paper-and-pencil format. All participants completed the scale during the first week of an introductory statistics course. *Achievement* in statistics was measured at the end of the course during the exam session.

### Data Analysis

Preliminarily, we tested the unidimensionality of the PRS evaluating local dependence (LD). LD is an excess of covariation among item responses that is not accounted for by a unidimensional IRT model and it was assessed using the  $\chi^2$  LD statistic (Chen & Tiessen, 1997), computed by comparing the observed and the expected frequencies in each of the two-way cross tabulations between responses to each pair of items. This diagnostic statistic is approximately distributed as standardized  $\chi^2$ . Given this approximation, as a rule of thumb, values of 10 or greater indicate the presence of LD.

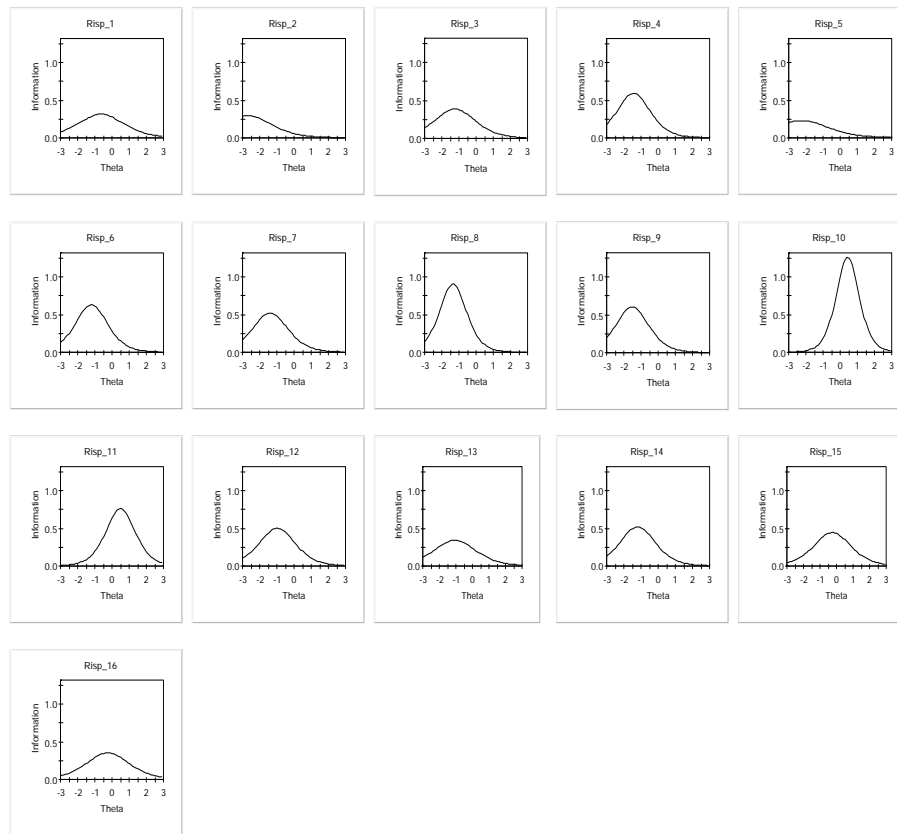

After having verified this assumption, unidimensional IRT analyses were performed. IRT models use the original response data for estimating probabilities of responses as a function of the latent trait  $\theta$  (i.e., in the current study, probabilistic reasoning), which is defined as a continuous variable that conventionally has a mean of zero and *SD* of 1.0. This function describes the relation between the probability of endorsing a response given not only the respondent's level of  $\theta$  but also the item's characteristics. A model with two parameters (2PL) was tested in order to estimate the item difficulty and discrimination parameters. The parameters were estimated by employing the marginal maximum likelihood estimation method with the Expectation-Maximization (EM) algorithm implemented in the IRTPRO software (Cai, Thissen, & du Toit, 2011). In the 2PL model, the two item parameters are item difficulty and item discrimination. The item difficulty parameter ( $\beta$ ) or "location" represents the latent trait level corresponding to a .50 probability of correctly endorsing the item. The item discrimination parameter ( $a$ ) or "slope" represents the item's ability to differentiate between people at contiguous levels of the latent trait. This parameter describes how rapidly the probabilities change with trait levels. In order to test the adequacy of the model, the fit of each item under the 2PL model was tested computing the  $S\chi^2$  statistics. Additionally, for each item was calculated the IIF, graphically represented by the Item Information Curve (IIC), that describes the amount of information that a particular item provides across the entire continuum of the latent construct, and it depends on both the discrimination and location parameters. Thus, we used IIFs to select the items that conveyed the higher amount of information along the range of the trait measured by the PRS, looking at the area above the IICs, which equals both the size of the  $a$  parameters and the spread of the  $b$  parameters. Once the shortened scale was defined, all the above described analyses were repeated for the brief scale in order to confirm the item and test psychometric properties. In particular, we investigated the reliability of the shortened scale. IRT makes it possible to assess the measurement precision of the test through the TIF. TIF is generated by aggregating the IIFs of items in a single measure and it allows to compute the information ( $I$ ), that is, the expected value of the inverse of the standard error (*SE*),

provided by the test at each level of the trait. Thus, the more information the test provides at a particular trait level, the smaller the error associated with trait estimation and the higher the test's reliability. Graphically, the TIF shows how well the construct is measured at different levels of the underlying construct continuum, and the peak of the TIF is where measurement precision is greatest. Regarding validity, Pearson product-moment correlations were computed.

## Results

Preliminarily, we tested the unidimensionality of the probabilistic reasoning construct, a fundamental criterion underlying IRT models, evaluating the presence of LD. The results confirmed that a single factor model adequately represented the structure of the scale, as none of the LD statistics were greater than 10. Additionally, the factor loadings ranged from .54 to .80. Each item had a non-significant  $S-\chi^2$  value, indicating that all items fit under the 2PL model. Concerning the difficulty parameters ( $b$ ), the results showed that the parameters ranged across the continuum of the latent trait from  $-2.68 \pm .53$  to  $.49 \pm .12$  logits (i.e., the logarithm of the odd, that is, the ratio of the probability of producing a correct response and the probability of responding incorrectly). Compared to the difficulty of the original scale ( $-2.97 \pm .5$  to  $-.07 \pm .08$  logits), results showed that the parameters spanned a wider range of the latent trait. With regard to the discrimination parameters ( $a$ ), following Baker's (2001) criteria, all items showed adequate discrimination levels ( $a$  values over .60). Having verified the preliminary assumptions for IRT modelling, we looked at the IICs to select the items that conveyed the higher amount of information along the range of the trait measured by the open-ended PRS (see Figure 1). The figure clearly shows that items 1, 2, 3, 5, 13, 15 and 16 provide lower amount of information.

Consequently, we retained nine items and we repeated the analyses for this shortened version of the PRS scale with an open-ended format. None of the LD statistics were greater than 10, indicating the absence of LD. All factor loadings were significant, ranging from .49 to .83. Each item had a non-significant  $S-\chi^2$  value, indicating that all items fit under the 2PL model. Concerning the difficulty parameters ( $b$ ), the results showed that the parameters ranged from  $-1.57 (\pm .29)$  to  $.46 (\pm .11)$  logits across the continuum of the latent trait. With regard to the discrimination parameters ( $a$ ), all items were above .60, indicating adequate discriminative power. Thus, still concerning item difficulty, the shortened version showed that the items had a low-medium level of difficulty. Nonetheless, the discriminative measures showed that the items could discriminate individuals with different trait levels.

**Figure 1: Item information curve (IIC) of the original 16-item PRS open format. Latent trait ( $\theta$ ) is shown on the horizontal axis and the amount of information and the SE yielded by the test at each trait level is shown on the vertical axis**

Next, we investigated the TIF that provides test reliability estimations indicating the precision of the whole test for each level of the latent trait. As shown in Figure 2, from 2 standard deviations below the mean to 0.5 above the mean (fixed at 0), the amount of test information was equal to or greater than 4 indicating that the instrument was sufficiently informative for this range of the trait. Thus, compared to the original scale that adequately measured low levels of probabilistic reasoning ability, the PRS-B accurately measures a wider range of the underlying trait.

**Figure 2: Test information function of the Probabilistic Reasoning Scale-Brief**

Finally, we looked at the validity of the scale. Table 1 presents descriptive statistics for all measures in the study, and the relations between the PRS-B, and all other variables. As expected, in line with the original scale, the PRS-B was significantly and positively correlated with mathematics skills and subjective numeracy, and negatively with mathematics anxiety. Concerning the relationship between PRS-B and statistics achievement, we found a significant positive correlation.

5. STATISTICS ACHIEVEMENT	.28**	.18*	-.15*	.09	--
M (SD)	5.99 (2.25)	22.38 (3.69)	23.39 (5.76)	32.14(6.70)	22.63 (3.49)

\*  $p < .05$ ; \*\*  $p < .01$ ; \*\*\*  $p < .001$

**Table 1: Descriptive statistics for the measures, and correlations between the PRQ-B and MPP, AMAS, SN, and statistics achievement**

To ascertain the predictive value of probabilistic reasoning as measured by the PRS-B, we tested a regression model in which the PRS-B was entered as a predictor of statistics achievement along with math competence (MPP), math anxiety (AMAS), and subjective numeracy (SN). The results showed that when all predictors were entered in the regression analysis together ( $F(4,133)=3.29$ ,  $p=.013$ ;  $R=.30$ ;  $R^2=.09$ ), the PRS-B was a significant predictor of statistics exam performance ( $\beta =.26$ ;  $p=.009$ ), whereas the MPP, SN, and AMAS did not significantly predict statistics achievement.

## Conclusion

In this study, we presented the PRS-B scale to assess probabilistic reasoning skills. Applying IRT, we obtained a shorter version of the original PRS, where all remaining items had good discriminative power and they measured a large spectrum of the trait which covered a wider range than the original scale. Additionally, the PRS-B accurately measures average levels of probabilistic reasoning ability, and it is helpful in identifying individuals who have difficulties in this domain. Finally, the validity results confirm that the shortened form replicates the pattern of relationships established for the construct as measured by the long form, with positive relations with mathematics and statistics skills and subjective confidence, and a negative relationship with mathematics anxiety. In conclusion, the PRS-B could be a useful tool in educational contexts, as well as in research.

# An alternative method to compute confidence intervals for proportion

Antonio Francisco Roldán López de Hierro, María del Mar López-Martín and Carmen Batanero

University of Granada, Spain; [aroldan@ugr.es](mailto:aroldan@ugr.es), [mariadelmarlopez@ugr.es](mailto:mariadelmarlopez@ugr.es), [batanero@ugr.es](mailto:batanero@ugr.es)

*Keywords: Proportion, confidence level, confidence interval, interpretation.*

## Introduction

Confidence intervals are a main inferential procedure with many applications to real life, such as studying the percentage of voters will finally vote for a particular political party or the proportion of the population that suffers from asthma. This topic is taught in Spain to high school students in the Social Sciences specialty and in most of university grades. Since the available time for teaching is scarce, students are mainly taught the computing procedure, with no much attention to interpretation of results. Olivo, Batanero and Díaz (2008), and references therein, described some difficulties appearing in students' interpretation of confidence intervals for proportion.

The aim of this paper is to present an alternative methodology to compute confidence intervals for proportion by using the approach due to Wilson (1927). It would be of interest for students to discover that there is not a unique way to compute such interval. With the help of computers, by comparing Wilson's procedure to classical one, students would be able to improve their interpretation of the confidence interval for proportion and its confidence level.

## Usual methodology to determine confidence intervals for proportions

Below, we summarize the usual procedure for computing the confidence interval. Suppose we are interested in estimating the proportion  $p$  of individuals in a population that satisfy certain condition. We take a random sample of the population, and observe the number  $X$  of individuals in the sample that verifies that property, which follows a Binomial distribution of parameters  $n$  and  $p$ . When  $n$  is large enough, we approximate this distribution by the normal distribution  $X \approx \tilde{X} \mapsto N(np, npq)$ , where  $q = 1 - p$ , and it can be typified as  $(\hat{p} - p)/\sqrt{pq/n} \mapsto N(0,1)$  where  $\hat{p}$  is the sample proportion defined as the number of the successes divided by total number of observations in the sample. Let denote by  $1 - \alpha$  the confidence level (usually  $1 - \alpha \in \{0.9, 0.95, 0.99\}$ ) and let  $z_{1-\alpha/2} > 0$  be the unique positive real number such that  $P(-z_{1-\alpha/2} < Z < z_{1-\alpha/2}) = 1 - \alpha$ , where  $Z$  is any random variable following the standard normal distribution  $N(0,1)$ . Then the following approximation can be considered:

$$P\left(-z_{1-\alpha/2} < \frac{\hat{p} - p}{\sqrt{p(1-p)/n}} < z_{1-\alpha/2}\right) = 1 - \alpha. \quad (1)$$

Since  $p$  is unknown, we replace it by its maximum likelihood estimator,  $\hat{p}$ , from which it is easy to deduce that the confidence interval for  $p$ , at the confidence level  $1 - \alpha$ , is

$$IC(p) = \left[ \hat{p} \pm z_{1-\alpha/2} \sqrt{\hat{p}(1-\hat{p})/n} \right]. \quad (2)$$

The advantage of this expression is that it is very simple to use in practice and it produces good results. Its main weakness is that it has been obtained through a process in which, without apparent justification, the true value of  $p$  has been replaced by its estimator  $\hat{p}$ . This replacement transforms a

non-linear problem into a linear problem. One of the most important drawbacks of expression (2) is that this formula does not reach the confidence level.

### Wilson's methodology to determine the confidence interval for proportion

This method proposes to solve the equation (of second degree after squaring):

$$\frac{\hat{p} - p}{\sqrt{p(1-p)/n}} = z_{1-\alpha/2}$$

before replacing  $p$  by  $\hat{p}$  in the denominator. Its two solutions determine the extremes of the confidence interval for proportion, which are:

$$IC_W(p) = \left[ \frac{2n\hat{p} + z_{1-\alpha/2}^2 \pm z_{1-\alpha/2} \sqrt{z_{1-\alpha/2}^2 + 4n\hat{p}(1-\hat{p})}}{2(n + z_{1-\alpha/2}^2)} \right]. \quad (3)$$

Since this formulae is more complex than (2), we propose to use a spreadsheet to generate a lot of random samples of distribution  $B(n, p)$  (for instance, 1000 or more), when  $n$  and  $p$  are previously set by students. By using that random samples, we can compute both (2) and (3) intervals, and to determine how many of them indeed contain the true value of  $p$ . This comparison will help students to understand that the correct interpretation of confidence interval relies on the methodology, but not on the interval: when lots of intervals are randomly generated, we trust that  $100(1 - \alpha)\%$  will contain the (unknown) true value of the proportion  $p$ . Furthermore, we are interested on overcoming the wrong student's usual affirmation that establishes that, after computing the confidence interval, the probability that  $p$  belongs to such interval is the confidence level. This novel view-point could be of interest for both undergraduate and graduate students.

To compare both methods, we present the results of 10000 and 1000000 simulation with  $n = 30$  (see Table 1). We highlight that only around the 88% of the intervals constructed using (2) contains the real value of  $p$  and the greater confidence of Wilson's method.

Usual method		Wilson's method	
$N = 10000$	$N = 1000000$	$N = 10000$	$N = 1000000$
87.19%	87.54%	94.88 %	95.23 %

**Table 1: Proportion of confidence intervals in simulation containing the true value of  $p$**

# Primary school students reasoning about and with the median when comparing distributions

Susanne Schnell<sup>1</sup> and Daniel Frischemeier<sup>2</sup>

<sup>1</sup> University of Paderborn, Germany, Susanne.Schnell@math.upb.de

<sup>2</sup> University of Paderborn, Germany, dafr@math.upb.de

*Statistical reasoning can be enhanced at an early stage by facilitating informal statistical reasoning and developing conventional measures based on individual conceptions. This paper aims at identifying young students' conceptions of the median and their relations to its definition. For this, we present a design research study with grade 3 students (age 9) focusing on the comparison of two groups. The qualitative analysis of complementary interviews shows that young students already develop an initial understanding of the median but struggle to find the conventional reference for the middle. Consequences will be drawn for further design cycles.*

**Keywords:** statistics education, early statistics, primary school, comparing groups, median

## Introduction: Early statistics in German curriculum

Statistical literacy is a fundamental component for active citizenship (Engel, 2017). Some facets of statistical literacy can be approached as early as primary school – an overview is presented in Leavy, Meletiou-Mavrotheris, and Paparistodemou (2018). In Germany, nation-wide standards for primary education in mathematics require students to gain competences in dealing with “data, frequency, and chance” (Hasemann & Mirwald, 2012). The core idea is to develop conceptual fundamentals, e.g. by posing statistical questions, collecting data, and creating and interpreting representations of data (Hasemann & Mirwald, 2012). German textbooks and teaching materials for primary school, however, often emphasize singular aspects such as reading a diagram rather than introducing context-rich and complex data analysis projects as sustainable teaching-learning arrangement (Bakker, 2004). Such an arrangement aims at developing students' competences in drawing and dealing with informal statistical inferences (Makar, Bakker, & Ben-Zvi, 2011) and building on existing informal conceptions in order to develop conventional ideas (Bakker, 2004). Hence, researching initiated learning processes is an important task (Makar, 2014). This paper presents a design-based research project (Prediger et al., 2012) which was conducted over four cycles so far in order to develop a statistics teaching-learning arrangement for classrooms in German primary schools. After summarizing theoretical considerations, the main design principles and framework of the teaching-learning setting are discussed. Lastly, we will present empirical insights of students' statistical reasoning about and with the median from interviews with students grade 3 (age 9) conducted after the whole-classroom activities.

## Statistical projects in primary school

Going beyond calculation and algorithms in statistics education means enabling students to deal with statistical inquiries and applying the phases *problem*, *plan*, *data*, *analysis* and *conclusions* of the PPDAC-cycle (Wild & Pfannkuch, 1999). Especially at the starting point of a statistical inquiry – e.g., when posing statistical questions – the desire arises to not only consider the distribution of one variable, but to look for a relationship between two or more variables. So, for example, the question whether third graders tend to have more games on their smartphones than fourth graders

leads to the comparison of two groups. While easily motivated, group comparisons are also sophisticated statistical activities taking into account many of the fundamental statistical ideas like data, variation, representation, etc. (Burrill & Biehler, 2011). Frischemeier (2017) identified several important and sustainable group comparison elements like center, spread, skewness, shift, p-based and q-based comparisons. While these concepts can be quite complex, the fundamental ideas behind them can be addressed already in primary school. Informal comparisons are a fruitful task to provide in-depth insights into students' conceptual development and informal statistical reasoning (e.g. Schnell & Büscher, 2015, Makar, 2014). In this paper, we focus on using (informal) conceptions of the median as well as visual features of distributions for comparing groups in early statistics.

To describe the center of a distribution is a key idea of statistics (e.g. Bakker, 2004; Makar, 2014). The concept of the median can be introduced on an enactive level via “animated statistics” in the sense of embodied cognition by Lakoff & Núñez (2000). In this case the students are statistical units themselves, line up in an ascending order in regard to a certain attribute (e. g. their height) and identify the middle. Even the more formal procedure of determining the median (sorting values and finding the middle value) is easily and non-formally presentable, but the interpretation and a deeper conceptual understanding can be challenging (Mokros & Russel, 1995) as it is interwoven with ideas like representativeness and typicality. However, these ideas can be pre-formally existent from even young students' everyday experiences (Mokros & Russel, 1995). Mokros and Russel (1995) identified approaches to the average, which include among others the average as an algorithm without predominant focus on contextual interpretation or the average as midpoint which is chosen as representative of the data and draws on the ‘middle’ which alternately is the median, the middle of the X-axis or the middle of the range. To be able to interpret the median correctly and in a meaningful way, it has to be understood as a value in reference to the rest of the distribution (e.g. cutting the data set in two halves). Overall, even students who are familiar with formal ways to determine the median sometimes do not apply it when comparing distributions (e.g. Watson & Moritz, 1999; Konold et al., 1997). This might be due to a lack of understanding that measures such as the median are representative of a distribution (Konold et al., 1997). However, Makar (2014) shows how even young students of age 8 can be supported in developing a fundamental understanding of the median and using it for informal inferential reasoning when presented with an adequate teaching-learning arrangement. The key is to give students room to develop informal ideas which serve as important base for building foundational knowledge of statistical concepts (Makar, 2014; Bakker, 2004; Smith, diSessa, & Rochelle, 1993).

Especially in terms of visual aspects, young students draw on a variety of different strategies to describe and compare distributions (e. g. Watson and Moritz, 1999). For instance, they focus on ‘hills’ to describe the shape of the data (Bakker, 2004). To facilitate a proto-concept of center, Konold et al. (2002) introduced so-called modal clumps as “a range of data in the heart of a distribution of values” (p. 1) in order to find ways to identify the center in stacked dot plots and “allow students to express simultaneously what is average and how variable the data are” (p.1). Bakker and Gravemeijer (2004) build on these concepts to lead students from a local perspective (focusing on singular dates such as the minimum) to a global perspective on distributions (with a

certain shape, spread etc.) and see modal clumps as proto-concepts not only for center but also for spread and therefore provide students with the opportunity to compare two distributions.

Overall, our aim is to design and realize a teaching-learning arrangement to enhance the statistical reasoning of primary school students and to enable them to compare groups with proto-concepts like modal clumps and concepts like medians when working on statistical projects. This paper focusses on exploring which concepts of the median were developed by the children during the teaching-learning unit and applied in the interview. Therefore, the research question is: *Which conceptions of the median do students verbalize in the interviews and what is their (visual) point of reference for the median?*

## Research Design

### Methodological framework: Design Research

This study is situated in the methodological framework of topic-specific didactical design research (Prediger et al., 2012). Thus, it aims at designing a specific teaching-learning arrangement for data competence in primary school on the one hand, and the development of local theories of teaching and learning conceptual basics at an early age on the other hand. These intentions are addressed in iterative research cycles of (re-)designing, implementing, and analyzing the materials (Prediger et al., 2012). So far, four cycles were conducted, exploring different settings with whole classes and special interest groups in grade 3 and 4. After the classroom-activities, additional interviews for in-depth analysis of students' reasoning were conducted.

### Design principles and teaching-learning arrangement

For the design of the teaching-learning unit we implemented several recommendations for the design of Statistical Reasoning Learning Environments (Garfield & Ben-Zvi, 2008) such as using real data sets and using digital tools like TinkerPlots (Konold & Miller, 2011), which can help young students to manipulate and modify the data in regard to a specific question. Furthermore, we facilitated collaborative work on statistical projects (first with small datasets, later with larger datasets), introduced the students to data analysis concepts on different representation levels (enactive, iconic, symbolic) and promoted the use of informal concepts such as modal clumps (Konold et al., 2002).

In the following we refer mainly to the version of the teaching-learning arrangement by Breker (2018) from the last design research cycle in which 22 third grade students participated. All of the students have no specific statistical pre-knowledge – they have only been introduced to the reading and interpreting of pie graphs and tallies. The teaching-learning arrangement consisted of seven modules spread over 13 lessons (45 minute each):

#### Module Content

- |   |                                                                                               |
|---|-----------------------------------------------------------------------------------------------|
| 0 | Getting to know each other                                                                    |
| 1 | First basics in data analysis and getting to know the questionnaire                           |
| 2 | Statistical representations on different representational levels (enactive, iconic, symbolic) |
| 3 | Introduction to data analysis with TinkerPlots and creating stacked dot plots in TinkerPlots  |

- 4 Getting to know modal clumps, medians and hatplots to compare groups
- 5 Group comparison projects: Preparing the posters
- 6 Presentation of the group comparison posters
- 7 Conclusion of the project

The median was introduced in module 4. As mentioned above, one fundamental idea was to present data analysis concepts on different representation levels. Hence the median was introduced on an enactive level with animated statistics: The students were asked to line up in a row ascending by their height and determined the child in the middle. After completing a fill-in-the-blank text with the characteristics of the median, the teacher demonstrated how to use TinkerPlots to identify the median in a distribution. The median was then used by the students to compare different distributions.

Our aim was to investigate the ways in which the students use statistical concepts such as the median to compare groups in data sets in TinkerPlots after completing the teaching-learning arrangement in class. Hence we conducted subsequent interviews with a convenience sample of participants. Here, we provided them with a real data set including variables about leisure time activities and media use of about 680 primary school students (grade 3 and 4). The participants' task was to investigate whether the third or the fourth graders have more games on their smartphones. The interview consisted of two main activities with regard to the task: First the students were asked to conjecture two dot plots (grade 3 vs. grade 4) based on their expectation. Second the students were asked to use TinkerPlots to compare the groups of third and fourth graders in the real data set.

### **Data collection and analysis**

Ten students participated in the interview study of cycle 4 after they completed the teaching-learning arrangement with their class. In the interviews, the students worked in pairs of two. All interviews, including the activities in TinkerPlots, were recorded and fully transcribed. The analysis was conducted under the interpretative paradigm, scrutinizing the transcripts for sequences in which the students use the median and then reconstructing their cognitive activities and conceptions.

## **Findings**

### **The middle of what? – The case of Paula and Linda**

Paula's and Linda's initial hypothesis is that fourth graders have more games on their smartphone. After creating two conjectured dot plots, the researcher asks the students to explain the meaning of the median.

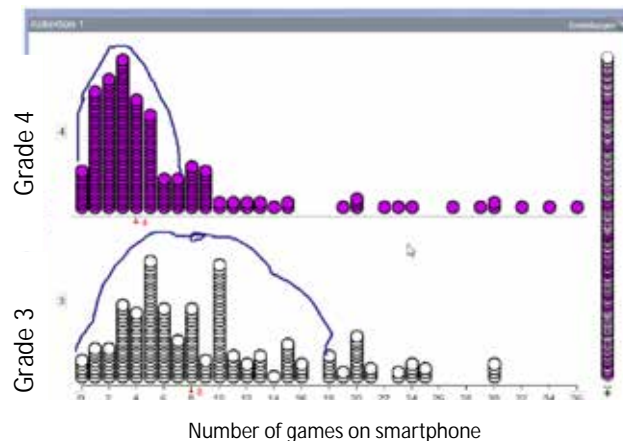

80 R: Could you maybe explain it again: what is the median, Paula?

81 Paula: The center point of the/ well it's the center of the dot plot.

Paula calls it the 'center point' and seems to be aware that she has to specify the point of reference of the center. Her offered reference 'the center of the dot plot' (line 81) is ambiguous as it could refer to the X-axis, the range of data dots or the distribution of data dots (similar to *average as midpoint*, Mokros & Russel, 1995). For determining the median, she counts only the columns of dots (with the same value) rather than every single dot, which equals determining the center of the

range. Both girls interpret this median correctly in terms of the higher median indicating more games for fourth graders.

When introduced to the real data set, the girls first determine and interpret the hills. Asked to summarize the findings in regard to the overall question (line 218), Paula argues with the median which they have not determined for this distribution, yet.

**Figure 1: Paula and Linda's TinkerPlots screen with drawn-in hills and later added medians  
(median of 3<sup>rd</sup> graders: 8, median of 4<sup>th</sup> graders: 4)**

- 218 R: Okay. Good. Now, what did you find out for your question, when you look at the hills? 3<sup>rd</sup> or 4<sup>th</sup> graders – who has more games on the smartphone? (...)
- 223 Paula: 4<sup>th</sup> graders. (...) Because 4<sup>th</sup> graders moved farther to the right with their dots and if you take the exact center, now, only of the dots, not of the stripes [i. e. X-axes]. Because otherwise the median would be the same. Just from the dots, the median of the 4<sup>th</sup> graders is farther in the middle than of the 3<sup>rd</sup> graders.
- 224 Linda: Yes, definitely. But really, if you just take half somehow, then it really looks like the 3<sup>rd</sup> graders were furth/ had more (*incomprehensible*)

Describing how the distribution of fourth graders “moved” more to the right in comparison to the third graders, Paula describes *the center* as a point of reference (line 223). It is likely that Paula is not thinking of the correctly determined median (which - in contrast to her expectation - is smaller for the fourth graders than for the third graders), but rather her individually determined center of the range. However, her remark about the X-axis shows again awareness of the reference for this value. While both children are at first confident in their answer of the 4<sup>th</sup> graders having more games, Linda mentions doubts in line 224. By “taking half”, she could either refer to the left half of dots (e.g. the data between 0 and 16 games) or possibly to the lower “half” (e.g. the range of 0 to 36 games but cutting of each column above a certain frequency). This idea is not followed up upon, though.

When the girls determine the median in TinkerPlots, it seems to differ from their expectation:

- 238 Paula: They just took it of the hills. And in the hills, 3<sup>rd</sup> graders have more.
- 239 Linda: Right.

- 240 R: In the hills? I didn't get that.
- 241 Paula: So the median of the hills.
- 242 R: The median of the hills? What is that/
- 243 Linda They didn't use all of them. They just drew it within the hills. (...)
- 247 Paula Yes, but otherwise the [median] of the 4<sup>th</sup> graders would be much further in the middle and the one of 3<sup>rd</sup> graders, too. (...)
- 250 Linda If you cut off the hill completely, then it should be sitting somewhere here, and of this one here at 14, 12, 16. Somewhere there. (...)
- 271 R: So, if you only look at the medians, who has more games on the smartphone?
- 272 Paula: Yes, in this case, where they used only the hills, it's the 3<sup>rd</sup> graders. But if you had done it without the hills, it would be the 4<sup>th</sup> graders.

Paula explains the unexpected median by the way she thinks it was determined in the program, i.e. by determining the center of the hill's width (cf. figure 1). Thus, she still interprets the TinkerPlots median as referential but differing from the learned definition. In line 247, Paula suspects the true median of the 4<sup>th</sup> graders to be farther in the middle (i.e. right). This indicates that she stays with her initial interpretation of the median as center of the range. In line 250, Linda suggests a manipulation of the data by "cutting of the hill". As she says the median would then be between 12 and 16, she might refer to cutting of the dot plot horizontally, thus evening out the number of dots per number of games and making Paula's procedure of determining the median correct. Thus, Linda twice offers ways to manipulate the data set and thinks about the effects on the median. Overall, the girls use the idea of two different medians in order to support her initial expectation that fourth graders have more games on the phone (line 272).

In regard to the research question, the girls developed conceptions of the *median as the middle of the range* and *median as the middle of the modal hill*. They are very consistent with their way of determining it, which might have its roots in the animated statistics activity. It is remarkable that they consider different options of manipulating the data set and their effects on the median, which hints that they perceive it as a value that is closely connected to the distribution and that has representative value. By assuming that TinkerPlots uses the hills' boundaries rather than the whole distribution for determining the median, the girls establish a pre-formal connection between the visual approach and the calculated measure.

### **Additional interpretations of the median**

The students in the interview study showed a variety of different conceptions of the median:

- Layla and Sandra as well as Burak and Tarik call the median "the middle (of the dots)" (LS\_line 483, BT\_line 103) but do not specify it further other than using the learned procedure to determine it ⇒ *median as unspecified middle*
- Johannes and Nils interpret it as the center with "roughly the same amount [of dots]" in each half (JN\_line 53) ⇒ *median as the middle of two halves*

- Lara and Lia seem to make a connection between the modal value and median “A median is the middle of the biggest. Of the biggest amount.” (LL\_line 171) à *median as the middle of modal clump*

## Conclusion

This paper aimed at identifying young students' conceptions of the median and their relations to the conventional measure (Bakker, 2004). The analysis shows how the students are integrating visual and calculated aspects of the distribution in order to compare groups. Building on Mokros and Russell (1995), we could identify several conceptions of the median which draw on different references in the data set: *median as middle of the range*, *median as middle of the modal hill*, *median as the middle of two halves*, *median as the middle of modal clump or column* and *median as unspecified middle*. While all pairs were able to interpret the shift of the medians correctly, the in-depth analysis shows their struggle with the referential concept. Even though these conceptions were not yet in-line with the conventional conception of the median, they serve as important starting points for the development of more formal conceptions (Smith, diSessa, & Rochelle, 1991). Overall, the teaching-learning arrangement clearly supports young students in informal reasoning about statistical concepts while comparing groups. For instance, Linda's considerations of manipulating the data set in order to change the median are promising starting points for further design cycles.

Another implication from the analysis is to be careful when introducing the median via animated statistics. When choosing this way, a scale should be prepared so that the distances between the children (i.e. data dots) become apparent and stacked distributions should be discussed. For a hypothetical learning pathway, we suggest to introduce first the modal clump as main area in the heart of the data distribution and then the median as a special value in relation to the modal clump, indicating the center of the distribution. Next discuss different distributions in which the position of the clump and the median differ. These ideas will be realized in the next design cycle of the teaching-learning arrangement.

# A case study on design and application of creative tasks for teaching percentage bars and pie charts

Balgeum Song<sup>1</sup>, Kyeong-Hwa Lee<sup>2</sup> and Yeong Ok,Chong<sup>3</sup>

<sup>1</sup>Graduate School of Education, Seoul National University, Korea; bgsong@snu.ac.kr

<sup>2</sup>Seoul National University, Korea; khmath@snu.ac.kr

<sup>3</sup>Gyeongin National University of Education, Korea; yochong@ginue.ac.kr

*Keywords: Mathematical creativity, percentage bar, pie chart, statistical thinking.*

## Introduction

There is a need to discuss on teaching and learning situations which include graph comprehension and construction to promote students' conceptual understanding of graphs, however, little attention was given to this until the present day (Friel, Curcio, & Bright, 2001). Since several research have indicated that creative tasks and teaching strategies effectively enhance students' conceptual understanding and mathematical thinking (Luria, Sriraman, & Kaufman, 2017), in this study, we investigate how creative tasks and instructional strategies for lessons on percentage bars and pie charts are used to elicit students' growth in conceptual understanding and statistical thinking.

## Theoretical framework

### Percentage bars, Pie charts and Statistical thinking

Percentage bars and pie charts show how sectors constitute a whole (Reys et al., 2012). Learning these graphs relates to percentage, proportional relationship between the area of each sectors and their percentages, and interpreting graphs connecting data and the context (Reys et al., 2012; Curcio, 1987). In terms of statistical thinking, it is necessary to guide students to develop global view from local view as we can discern the general feature of the data set with global view (Ben-Zvi & Arcavi, 2001).

### Mathematical creativity

Four main components of mathematical creativity are fluency, flexibility, originality and elaboration (Luria et al., 2017). Here we define creative task as open-ended and multiple solution task which can be performed in various ways, inclusive of informal method and representations, especially, applying one's experience and prior knowledge using fluency, flexibility, originality and elaboration.

## Methodology

In this study, case study methodology was used and a class of 28 sixth-grade students participated. These pupils had not learnt about percentage bars and pie charts before. The first task asked students to discuss the claim which includes certain percentage value and to visualize given percentage value. The second was about construction of percentage model from given data table. In the last task, each group of students was given a percentage bar or a pie chart without label. They were asked to infer the percentage and the item of each sector and then interpret the given graph. Discussions among students were conducted for social interaction. All teaching-experiment sessions were videotaped and recorded. These data were transcribed later for analysis. The students' individual worksheets were

collected. Researchers attended all lessons and recorded field notes. We established four phases of learning percentage bars and pie charts based on Curcio(1987)'s three levels of graph comprehension and Ben-Zvi and Arcavi(2001)'s research about the process of the construction of global view from local view. Students' responses and models were classified according to these four phases in order to verify if students' conceptual understanding and statistical thinking were improved.

Phase	Construction	Interpretation	
		Data	Context
0	Focused on context	Considering personal experience	
1	Focused on pointwise information	Considering appropriate context situation	
2	Focused on the difference between individual data	Comparison of the meaning of each part	
3	Focused on the proportional relationship among data	Suggestion of alternative, prediction, implication	

**Table 1: Phases of learning percentage bars and pie charts**

## Findings and Conclusion

The students constructed and developed percentage models, and interpreted percentage bars and pie charts using their fluency, flexibility, originality and elaboration in this study. Meanwhile, they showed increases in the phases of learning percentage bars and pie charts. If the tasks did not allow diverse approaches and representations using students' own method to perform the tasks, we believe that it would be hard to expect these increases. The findings showed that creative tasks with proper instructional strategies promote conceptual understanding and statistical thinking by stimulating students' creativity. Furthermore, the analysis indicated that the creative tasks provide various learning opportunities for students who differ in their levels. This study provides empirical evidence to support previous claims that the use of creative tasks and instructional strategies in the mathematics classroom enhance students' conceptual understanding and mathematical thinking (Luria et al., 2017).

This study is part of "Siheung City - Seoul National University Partnership for Primary/Secondary School Education Program" funded by Siheung City, Gyeonggi-do, Republic of Korea.

# Algorithms as a discovery process in frequentist approach to prediction interval

Jannick Trunkenwald and Dominique Laval

Université Diderot-Paris, France; [jannick.trunkenwald@yahoo.fr](mailto:jannick.trunkenwald@yahoo.fr) ; [dominique.laval@gmail.com](mailto:dominique.laval@gmail.com)

*This article deals with the contribution of algorithmic to introduce the frequentist approach to probability. Our attention is focused on teachers in training who have to perform a sampling simulation program in order to solve a probabilistic task. The mathematical work corresponding to this discovery process of the prediction interval is analysed in its semiotic, discursive, and instrumental dimensions, within each of involved fields (probabilities, descriptive statistics and algorithmic). Synergies and interactions between these various fields are taken into account. Methodological tools MWS (Kuzniak, 2011) and AWS (Laval, 2018) are used to lead this study.*

*Keywords: Algorithmic, Work Spaces, frequentist, probability, field*

## Introduction

In France, teaching of probability in upper school commences with a double approach: “combinatorial” and “frequentist”. This makes it possible to connect the abstract notion of probability to “real” world, as it is perceived through our senses. The approach of frequency derives from binomial distribution with a deductive reasoning based upon random variables. The approach of probability is based on sampling fluctuation with empirical observations of frequencies. We choose to analyse the introduction to sampling fluctuation that empirically establishes the prediction interval principle, which is the only formalized rule taught at 10<sup>th</sup> grade level. We make the choice to observe the work of teachers during a training course, by taking in account *instrumental*, *semiotic* and *discursive* dimensions. More particularly, this paper deals with existing interactions between fields such as probability and descriptive statistics, but also algorithmics during teacher’s work.

## Frequentist approach to sampling fluctuation

The 10th grade program in French school system leads to the discovery of sampling fluctuation with the following property: *Let  $p$  be the probability of success, and let  $n$  be the number of repeated random experiments. Any frequency  $f$  of success verifies  $f \in \left[ p - \frac{1}{\sqrt{n}}; p + \frac{1}{\sqrt{n}} \right]$  with at least a 95% level of confidence.* Nechache (2016) notices the absence in 10th grade of a probabilistic theoretical reference that would make it possible to approach this interval of fluctuation by deductive reasoning. The discovery process of this interval remains indeed at this stage, experimental and based on observation of samples which have the same size. Each frequency value corresponds to a sample obtained itself by repeating the considered random experiment. This is an empirical approach based on inductive reasoning. In addition, the “time cost” corresponding to the need of repeating the same experiment a large number of times entails a need for automation. And this idea is “facilitated” by using of computing which is based on a pseudo-random generator operation. Thus the “frequentist” approach requires consideration of three fields: probabilities, descriptive statistics and algorithmics.

A digital environment (“spreadsheet” or “programming software”) makes possible to reduce the time spent on repeating the random experiment. Specific skills are needed to digital field (algorithmic, syntax of machine language, user interface...), and the lack of computing expertise could cause

additional difficulties for students. It could also cause a meta-cognitive (or even cognitive) concern to teachers. Using digital field makes possible to automate an experimental protocol that requires the use of gestures, syntax, and specific modes of thinking. However, we can also question the specific contribution resulting from the use of a machine-implementable method, for a better comprehension of the frequentist approach (from a mathematical point of view). This question seems being even more important for teachers. Indeed, they are supposed to look closely at their practices. We can thus consider three main ways of exploiting a digital field to modelize the random experiment: - a spreadsheet; - the construction of “paper-and-pencil” algorithms and the actual implementation on the computer in order to test them; - the use of simulation algorithms or spreadsheet provided and already built. Each of these forms of use can be assimilated to an *instrumentalization* of computing or algorithmics *artifacts* to construct a “frequentist” approach in probabilistic or statistical fields.

We choose not to approach the spreadsheet case and to restrict the scope to algorithms. We believe that focusing on algorithms enables us to study the instrumental, semiotic and discursive dimensions which will be involved during mathematical and algorithmic work on sampling fluctuations. We thus seek to study the contribution of an *algorithmic thought* (Laval, 2018; Modeste, 2012) in the context of a mathematical work on probabilities and statistics. In particular, we think that writing the simulation algorithm corresponds to a higher stage of formalization for different involved statistical protocols, and that the role of “language” will take on particular importance in this sense.

### Observations carried out in teacher training

Training on the simulation of sampling fluctuation at 10th grade level is conducted during an internship at the French High School in Algiers on May 2018. Five groups of three teachers (A, B, C, D, and E) have to solve the following problem: “What is the probability that the distance between two points randomly chosen along a line segment  $S$ , is more than half the length of the segment  $S$ ?”.

We build on existing work previously undertaken by Nechache (2016) and Trunkenwald (2018), to consider this task as being representative of institutional expectations for the “frequentist” approach. It is possible to explore sampling fluctuation with a real repetition of the random experiment (case of strings of twines cut with scissors), but considering this long process with randomization by a human being choice, our hypothesis is that teachers will use a numerical simulation operating with a pseudo-random generator ( $Alea()$ ), which returns a random number between 0 and 1 simulating the position of a randomly selected point on the  $S$ -segment. The modelling work highlighting sampling fluctuation can find its formalized expression through a simulation algorithm. Indeed, the random experiment providing distance between two selected points can be simulated with  $|Alea() - Alea()|$  as computing instruction which can be considered as a *level 0 algorithm* used for each simulation of the random experiment. Another *level 1 algorithm* can be constructed from the *level 0 algorithm*, by repeating the random experiment to obtain directly a simulated frequency of success (Figure 1).

Figure 1: Level 1 and level 2 algorithms written in pseudo-code.

Running several times *level 1 algorithm* generates a list of frequencies, which can be represented as a cloud diagram (scatter plot). For this purpose, a third step can be envisaged in digital field: the *level 2 algorithm* (Figure 1) automating the layout of the cloud. Then *level 2 algorithm* is constructed from *level 0 algorithm*, by repeating the simulated frequency of success to draw directly the cloud.

The working groups do not have access to any pre-existing files to accomplish their task. But the algorithms they will design can be adapted for a later activity based on a roll of three dice. The groups manage more or less easily, with the help of the trainer when it is necessary, realizing a numerical model for the simulation of a frequency calculation. Only one group (the E) uses the spreadsheet, and only one group (the C) manages to finalize *level 2 algorithm*. Indeed, the transition from level 1 to level 2 corresponds to a tricky stage, especially the algorithmic writing of a statistical protocol that would consist in exploiting (on “paper”) the results provided by *level 1 algorithm*. Our hypothesis is that it is an epistemological obstacle linked to the encapsulation of an algorithm in another (principle of a procedural subroutine), in order to automate the execution of the first one. Other difficulties at the interaction of statistical and algorithmic domains are identified during the training session. We present (Figure 2) an excerpt from the transcription of exchanges between the trainer and the group B, concerning the implementation in *level 1 algorithm* of a counter.

Stagiaire 1 :	Le compteur moi je veux qu'il compte. Donc c'est la position...	Student 1	I want the counter to count. So, it is the position...
Tuteur :	D'accord. Donc comment on peut faire un compteur ?	Tutor :	OK. Then how can we make a counter?
Stagiaire 1 :	C'est... Donc il faut l'initialiser...	Student 1 :	It is... So, we have to initialize it...
Tuteur :	D'accord. L'initialiser à combien ?	Tutor :	OK. To initialize it at what value?
Stagiaire 1 :	Au départ de 0, puisqu'il n'y a aucun... mais...	Student 1 :	Starting at 0, because there is no one... but...
Tuteur :	Et quand est-ce que vous l'augmentez ?	Tutor :	And when do you increase it?
Stagiaire 1 :	C'est ça ! C'est la position où le mettre !... Est-ce que...	Student 1 :	That's it! It is the position where to put it!... Is it...
Tuteur :	Il va compter quoi ?	Tutor :	What will it count?
Stagiaire 2 :	Il va compter le nombre de cas favorables...	Student 2 :	It will count the number of favourable cases.
Tuteur :	... Voilà, donc à côté du « oui » vous l'augmentez de 1.	Tutor :	That's the point, then besides the “yes” you increase it of 1.
Stagiaire 1 :	... avant ou après ? ...	Student 1 :	... Before or after?...
Tuteur :	Avant ou après. Au même niveau.	Tutor :	Before or after. At the same level.
Stagiaire 2 :	On l'a mis ici... ça n'a pas marché.	Student 2 :	We put it here... It didn't work.
Tuteur :	Vous mettez compteur devient compteur + 1.	Tutor :	You set counter becomes counter + 1.
Stagiaire 1 :	On l'a mis, mais ça n'a pas...	Student 1 :	We did that, but it didn't...
Tuteur :	Où est votre compteur ?	Tutor :	Where is your counter?
Stagiaire 1 :	n.	Student 1 :	n
Tuteur :	Ah non, n ce n'est pas le compteur, c'est le numéro de l'étape.	Tutor :	No, n is not the counter, it is the step number.
Stagiaire 1 :	Oui c'est ça !	Student 1 :	Yes, it is!
Tuteur :	Vous devez ajouter une autre variable qui, elle, va compter les succès. n c'est autre chose... n c'est le numéro de votre étape parmi les 100 étapes.	Tutor :	You should set another variable which will count the achieved successes. n is another thing... n is the step number among all the 100 steps.
Stagiaire 1 :	Donc il nous faut deux... Donc on aura deux compteurs.	Student 1 :	So, we need two... So, we will have two counters.
Tuteur :	Il y a un compteur de l'étape en cours et un compteur du nombre de succès.	Tutor :	There is a counter for the current step and a counter for the number of achieved successes.
Stagiaire 1 :	Voilà ! Mais le compteur du nombre de succès c'est à la fin de la boucle ? Et après le sinon...	Student 1 :	Here it is! But the counter for the number of successes, it is at the end of the loop? And after the “else”.
Tuteur :	Il prend sa valeur à la fin de la boucle. Quand vous êtes sortis de la boucle.	Tutor :	It will get its value at the end of the loop. When you have got out from the loop.
Stagiaire 1 :	Voilà donc c'est après le « sinon ».	Student 1 :	Here it is, so it is after the “else”.
Tuteur :	La fin de la boucle ce n'est pas dans le « sinon ». La fin de la boucle c'est après le « Fin pour ».	Tutor :	The end of the loop is not in the “else”. The end of the loop is after the “End for”.

**Figure 2: Excerpt of a 8'14''record with group B**

In this excerpt the counter with its initialization, conditioned incrementation, and final exploitation appears as a complex construction. Its drafting is integrated into three levels of the algorithm script, with consideration of other instructions. Trainees try to locate a specific position which does not really exist for the counter... We observe a confusion between “success counter” and “simulation step counter”. Step counter is a “natural” process in statistics that becomes a difficulty in algorithmics. Finally, a similar difficulty appears in a confusion between the instructions “result value” provided by the counter, and “incrementation” of intermediate values used for its calculation. We can also

observe a difficulty between probability and statistics fields: S2 speaks of “favorable case” instead of “success achieved”.

In addition, transcripts of the session show difficulties related to the numerical modelling of the random experiment. Some difficulties appear in other groups, such as reluctance to use a pseudo-random generator, reference to the geometry field with consideration of lengths ratio  $|x_A - x_B|/L$  as a probability, and lack of definition for abscissa. All these observations show us the importance of interactions between various fields, as probability and statistics, but also with algorithmics, when introducing the frequentist approach of the prediction interval. We believe that an analysis of the mathematical and algorithmic work in these various fields with their interactions, can help us to refine our understanding of some difficulties encountered by trainees.

### **The choice of theoretical framework and research question**

Nilsson, Schindler, and Bakker (2017) presented a literature review of theoretical work apparent in Statistics Education Research (SER) over the past 11 years, encouraging educators and researchers to be explicit about their background theories and orienting: “in the reviewed articles there was no deeper theorization of computer assisted instruction in statistics. (...) In the 35 articles we found no theoretical attempts on a more specific level (...) such as guiding principles for designing tasks and sequencing tasks in a digital learning environment or frameworks for explaining and understanding the relationship between digital and analogue learning environments.”

Activities that involve a mathematical task associated with multiple domains can be analysed by considering that entities involved in the task appear under different semiotic, instrumental, and discursive representations. Some researchers have developed frameworks to conduct studies of these activities according to the type of studied representations. Duval (1993) named “registers” the representations organized in semiotic systems. Processes of handling and conversions are located inside and between these registers, and this description is also supplemented by the idea of “instruments” in the mathematical activity of students. Rabardel theoretical framework (1995) focused on this “instrumental approach”, and described the use of digital technologies to teach and learn mathematics in different contexts. Such a framework consisting of “objects” from mathematical fields with relationships between them, and different expressions or associated mental images, had already been addressed earlier by Douady (1986). However, some researchers have emphasized the inseparable development of instrument-related knowledge and mathematical knowledge, all in an *instrumental genesis*. An implementation of these issues for analysing articulation between the algorithmic and mathematical fields is presented in a didactic engineering of Laval (2018) based on the *Work Spaces* framework. And we wish to see taken into account the induced relations by instrumental and mathematical signs. Then we hypothesise that coordinating the activity in several fields could provide answers in this sense.

Indeed, in algorithmics the activity is located into an instrument for solving the mathematical task, with a specific system of signs for computer science. On the other hand, in mathematics the activity consists on solving the task from a mathematical point of view and using signs making it possible to understand and justify. Next, we have to choose an appropriate theoretical framework that can give meaning to the learner’s work during an activity involving several fields with their interactions, considering the *semiotic*, *instrumental*, and *discursive* dimensions specific to each field. We assume

that articulations between *Spaces of Specific Mathematical Work* (MWSs) (Kuzniak & Richard, 2014) and *Spaces of Algorithmic Work* (AWS) (Laval, 2018), will allow to study the different *geneses* of the *representamen* and *processes*, from the point of view of the learners' MWSs and AWS, but also to approach the interactions between the probability/statistics and algorithmics. We briefly present this theoretical framework in the following section. Then the research question of this article is how this framework can analyse a learner's work involving computer programming in a frequentist approach to the prediction interval. French programs also emphasize a potential contribution of algorithmic work to the understanding of mathematical concepts, which raises the question of interactions between domains in learners' activity (Lagrange & Laval, 2019; Laval, 2018).

### The working spaces MWSs AWS – First analyses

The methodological tools MWSs (Kuzniak, Tanguay, & Elia, 2016) and AWSs (Laval, 2018) help us to decompose intellectual perceptions at stake, during activity in mathematics and algorithmics fields. Three *instrumental*, *semiotic*, and *discursive dimensions* are considered, each generating a dynamic relationship between an *epistemological plane* and a *cognitive plane* (Figure 3).

Figure 3: Case of Algorithmic Space Work (Laval, 2018)

*Technological* (artifact), *semiotic* (representamen), and *theoretical* (referential) tools of *epistemological plane* can then be exploited using appropriate *schemes*. In this case, we respectively refer to *instrumental*, *semiotic*, and *discursive genesis*, which respectively produce *constructs*, *visualizations*, and *proofs* in the *cognitive plane*. The activation of two *geneses* can lead to a *circulation* between *dimensions* that carry them, which could sometimes be assimilated to the idea of modelling (Laval, 2018). We call “projection” of MWS<sub>s</sub> (or AWS) the restriction to a specific field of what we analyse in the *Workspace*. We write projections of the MWS on probability and statistic fields, as respectively MWS<sub>Prob</sub> and MWS<sub>Stat</sub>. In order to avoid visual overload, we present diagrams of these projections with a view from above. Points and bolded lines represent the different *discursive* (D), *instrumental* (I), and *semiotic* (S) *geneses*, as well as *circulations* in planes located between these *geneses*' axes.

The main interaction between MWS and AWS is related to the use of a pseudo-random generator. This *artifact* is first *instrumentalized* within AWS to build a simulation of the random experiment. The link between this construction and the associated formulation causes an I-D *circulation* and leads to a *discursive genesis* enriching the AWS referential. With reference to Laval (2015), algorithmic design work presents a triple *instrumental*, *semiotic*, and *discursive dimension* within AWS. We link this discursive dimension with the idea of “language”. Indeed, level 0, 1, and 2 algorithms are

formalized writes of experimental protocols. Algorithmic expressions in “natural” language, with their three encapsulated structures, then constitute an explicit formulation of the procedure to be followed in the statistical field to carry out a “frequentist approach” to the prediction interval. This explanation may be associated with the idea of proof. This consideration brings us back to *discursive genesis* which, according to Laval (2015), is confirmed when the program is able to run (at the first level of paradigm corresponding to an intuitive view of the algorithm).

It should be noted that this AWS *discursive dimension* tends to fade from “semiotico-instrumental” plan, when working with a spreadsheet tool, whose syntactic aspects are more related to nature of *artifacts* (even if *discursive dimension* is still activated from *cognitive plane* to mobilize tools of AWS *referential*). A complex construction with a spreadsheet can also reduce “intellectual visualization” of a phenomenon and thus *semiotic dimension*, to be limited to *instrumental dimension*. Finally, AWS loses all activity when the algorithm implemented in a digital environment is provided to learners to be executed and used without any modification work expected in its own structure. The algorithm is then reduced to an *artifact* ready to be *instrumentalised* in MWS projection on another field.

Simulation programs and dynamic tables are very active in the *instrumental dimension* of MWSs outside AWS. The “simulation programs” are instrumentalized as tools to build a statistical observation, within MWSstat (and within MWSprob if this construction shows properties resulting from chance).

### Case of algorithms written in “pseudo-code” of levels 0, 1, and 2

The *level 2 algorithm* aims to resume the experimental protocol of drawing a cloud diagram. We expect that trainees automate the cloud diagram of frequencies by improving *level 1 algorithm* which gives the simulation of a frequency. Then implementation of *level 2 algorithm* makes it possible to observe different clouds, and to conjecture the property of prediction interval. Figures 4, 5 and 6 present the exploded diagram (top view of MWSs and AWS) corresponding to designs and executions of each algorithm level. More specifically as regards interactions between probability and statistics, a more detailed description is presented in Trunkenwald (2018) for the chosen task.

**Figure 4: AWS, MWS<sub>Prob</sub>, and MWS<sub>Stat</sub> for level 0 algorithm (conception and exploitation).**

At level 0, the algorithm is designed in an instrumental genesis of the random generator artefact in AWS, simulating a distance between two randomly selected points along the segment. This numerical modelization generates a *discursive* validation of the random experiment simulation, through a *discursive genesis* in AWS. This *level 0 algorithm* is then used as a *technological tool* in MWS<sub>Stat</sub> through an *instrumental genesis* in MWS<sub>Stat</sub> (activating the *discursive dimension* by mobilizing frequency, and the *semiotic dimension* by mobilizing a type of data management). An experimental protocol for calculating a frequency is then constructed by running the *level 0 algorithm* many times (Figure 4).

**Figure 5: AWS, MWS<sub>Prob</sub>, and MWS<sub>Stat</sub> for level 1 algorithm (conception and exploitation).**

At level 1 (Figure 5), the frequency simulation protocol is totally automated. This algorithmic work generates a *complete circulation* in AWS. And the *level 1 algorithm* (new frequency simulation algorithm) is then used as a technological tool in MWS<sub>Stat</sub> through an *instrumental genesis* (activating the *discursive dimension* by mobilizing cartesian coordinate system). This protocol builds a frequency cloud diagram protocol by running the *level 1 algorithm* many times. This work generates a *semiotic genesis* in MWS<sub>Stat</sub> by *visualizing* the sample fluctuations. Supported by this new *semiotic link* between frequency and probability, this *semiotic genesis* in MWS<sub>Stat</sub> leads to a *semiotic genesis* in MWS<sub>Prob</sub> (“intellectual visualization” of fluctuations of chance).

**Figure 6: AWS, MWS<sub>Prob</sub>, and MWS<sub>Stat</sub> for level 2 algorithm (conception and exploitation)**

At level 2 (Figures 6 and 7), the cloud drawing protocol is totally automated. This algorithmic work generates again a *complete circulation* in AWS. And this *level 2 algorithm* (new cloud drawing algorithm) is then used as a technological tool in MWS<sub>Stat</sub> through an *instrumental genesis*. This *construction* of a new protocol leads a *complete circulation* in MWS<sub>Stat</sub> to build a conjecture of the prediction interval formula by inductive reasoning. This work generates a *discursive genesis* in MWS<sub>Stat</sub> with this new understanding of the interval meaning, in light of sample fluctuations. Supported by this new *discursive link* between frequency and probability, *discursive genesis* in MWS<sub>Stat</sub> leads to a *discursive genesis* in MWS<sub>Prob</sub> (understanding of the prediction interval formula meaning, in light of the frequentist approach of probability).

**Figure 7: Level 2 algorithm implemented on Albox**

## Conclusion

The three described phases allow us a construction by successive encapsulations of the simulation algorithm. These algorithmic steps also resonate with the experimental statistical protocol phases. And this semantic congruence finds its expression in a certain aspect of algorithmic work: the organization of in-blocks “subroutines” procedures.

The MWS<sub>S</sub> tool highlights interactions between the three considered domains: the *level 0 algorithm* designed in an interaction between the instrumental dimension of MWS and AWS. Then *level 0 algorithm* is executed in order to construct a new experimental protocol. The *level 0 algorithm* is then considered as a technological tool through an instrumental genesis in MWS<sub>Stat</sub>. Then *level 0 algorithm*, taken as theoretical tool in a discursive genesis of AWS, finalizes a new algorithmic object aiming to automate this new experimental protocol: the *level 1 algorithm*. Two new identical cycles of interactions between MWS<sub>Stat</sub> and AWS can successively generate the *level 2 algorithm*, which could establish a conjecture to frame the fluctuations. Then, this conjecture makes it possible to visualize in a semiotic genesis of MWS<sub>Prob</sub> the prediction interval, in order to activate the discursive dimension of MWS<sub>Prob</sub> to enrich the repository of the prediction interval property.

In addition, to highlight this dialectic of evolving interaction cycles between the three involved domains, our analysis can be used to design a prototype for teacher training session, or an activity for students, that avoid confronting learners with the simultaneous difficulties of different domains. Such a prototype can also be used as a remediation tool.

*With the aim of contributing to the study of the statistical knowledge of pre-service primary school teachers, here we present the creation of a system of categories of analysis to characterize the written reports of a group of students who carried out a task that reflected the five stages of the statistical investigative cycle. The analysis answers to a deductive/inductive process, since we look at the theory to understand our data and, at the same time, themes emerge that had not yet been described in the literature. Our contribution is a system of categories for the characterization of the statistical investigative cycle, which consolidates, refines and extends what has been published so far. The proposal presented here may be useful not only for researchers and teacher educators, but also for pre-service teachers themselves to understand the investigative cycle.*

*Keywords: Pre-service primary school teachers, statistics education, statistical thinking, investigative cycle.*

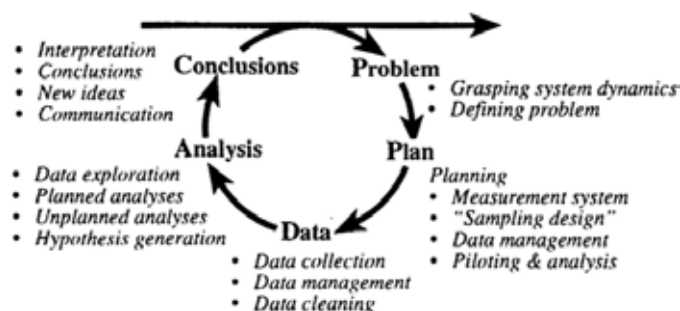

## Introduction and theoretical framework

In recent years the Spanish national curriculum has included statistics from the first year of primary school. At the end of compulsory education, students are expected to be able to formulate questions, select and use statistical methods, and draw conclusions based on data. It makes sense to assume that if this is what students are expected to achieve, teacher educators should train future teachers to be able to create educational instances focused on the development of such competences.

Batanero, Díaz, Contreras and Roa (2013) define statistical sense as the whole of statistical culture and statistical reasoning. This definition is based on the constructs of statistical literacy (Gal, 2002) and statistical thinking (Wild & Pfannkuch, 1999), including the idea of statistical reasoning as well as the fundamental ideas to be developed in statistical education. Wild and Pfannkuch (1999) propose four dimensions to characterize statistical thinking: the investigative cycle, types of thinking, the interrogative cycle, and dispositions.

Dimension 1, the investigative cycle represented in Figure 1, involves five stages consisting of problem, plan, data, analysis and conclusions. Dimension 2 includes types of thinking, and here Wild and Pfannkuch (1999) establish a general type and types fundamental to statistical thinking. In the latter, we find: a) recognition of the need for data to solve a problem that involves statistics; b) transnumeration corresponding to the idea of changing the format of the data in order to obtain new information; c) variation, which consists of noticing that variation is present in all the aspects of a problem involving statistics; d) a distinctive set of models; e) integration of context, statistical knowledge, and information on the data. Dimension 3 corresponds to the interrogative cycle, which involves five phases: imagining possible plans of attack or generating explanations, searching for

information and ideas, interpreting, checking against reference points (criticizing), and deciding what to believe or discard (judging). Finally, dimension 4 involves dispositions, which include skepticism, imagination, curiosity and awareness.

**Figure 1: The investigative cycle (Wild & Pfannkuch, 1999, p. 226)**

With the long-term aim of contributing to the understanding of the statistical knowledge of students starting on a primary school teacher education program, here we present the development of the system of categories used to characterize how a group of pre-service teachers approached the stages of a statistical investigative cycle (hereafter referred to as IC). Our contribution is a system of categories that consolidates, refines and extends the existing theoretical ideas.

### **Instrument and data collection**

According to Wild and Pfannkuch (1999), the IC is a coherent structure that links the different dimensions of statistical thinking. Since the aim of the present study was to create a tool to characterize the way pre-service primary teachers developed an IC, we set an activity that guided them explicitly through an investigative process. The activity consisted of six steps. The first five steps were related to the proposal of Wild and Pfannkuch (1999), and in the sixth step we asked the students to reflect upon the activity, identifying strengths and weaknesses of the investigative process they had carried out. The activity proceeded as follows:

1. *Define a topic of interest and a research question.*
2. *Justify the relevance of the research topic and of the research question.*
3. *Develop a data collection tool, justifying its construction and the questions that comprise it.*
4. *Analyze the data and present results.*
5. *Give a possible answer to the research question and establish conclusions.*
6. *Evaluate and reflect upon the whole process, identifying strengths and weaknesses.*

In February 2017, 134 students who had just started their four-year program in primary teaching at the Autonomous University of Barcelona were organized into 34 working teams of three or four members and developed the proposed activity in six 90-minute sessions. Our data consists of each team's written output, complemented by the classroom observations collected by the first author. This output is associated with a number: for example, G3 corresponds to Group 3.

### **Analysis**

The analysis took a deductive/inductive approach. First, in line with Wild and Pfannkuch (1999), we grouped data according to the different stages of the IC and the components of each stage (already

shown in Figure 1). The process was deductive in that, for each component, we looked for theoretical references to explain our data and from there we tried to organize it according to the theoretical specification of the component. While coding and grouping units of meaning according to their similarities and differences, themes emerged that had not yet been described in the literature. In this sense, the analysis process was also inductive.

Next, we present the analysis for each stage, and for each component – written in italics in the text – we introduce the categories used or created for our analysis. When the category is related to existing theory, we quote the reference. The references are introduced here rather than in the theoretical framework because we understand that they are part of our analytical framework. When the categories arose from the data, they appear underlined in the text, and together with the name given to the category we present a definition and examples where necessary.

### IC analysis: PROBLEM

The initial stage of the IC involves two components, with the first one *capturing the dynamics of the context*. Before defining the research problem, the teams justified their choice of research topic. Thus, an initial category arose – research rationale – with different subcategories:

- Relevance: their selection of the topic was justified by its relevance in the context. “We believe that reading is an essential source of knowledge. As future teachers, it would be important for us to spread the enjoyment of reading to the students. Therefore, we would like to know the literary preferences of our classmates.” (G1)
- Curiosity: their selection responded to their own curiosity about some aspect of their context, with no justification of its relevance. “By quickly observing our classmates, we detected that there are people wearing make-up and people that aren’t. We would like to dig deeper into the main reasons that have led them to wear make-up and find out at what ages they started to do so.” (G8)
- Unspecified interest: they stated that they were interested in the topic, without specifying why. “We have chosen this topic because it interested and motivated all the team members.” (G30)

When analyzing the component *problem definition*, we organized the written reports according to the preciseness of their problem formulation, creating three categories:

- Focus: the formulation established the topic they prioritized in their research.
- Purpose: the formulation established what they wanted to know about their topic of interest; however, they did not necessarily formulate a research question as such.
- Research question: they explicitly stated the research question that guided their investigation.

The definition of the problem could include some or all of these elements, as can be seen in the sentence we use to exemplify the different degrees of preciseness: “The topic we covered was books. More specifically, the interest in reading [focus]. The relevance of the chosen topic lies in the fact that for us, as future teachers, it would be interesting to find out how keen our classmates are on reading [purpose] so that we can influence future generations. Once we have chosen the topic, we will focus on the research question: Are we interested in reading? [research question]” (G10).

On looking at the nature of both the purpose and the research question and taking into account Makar and Fielding-Wells (2011), we distinguished two subcategories that respectively included questions

that either were or were not statistical in nature, depending on whether or not statistical work was involved. Regarding the type of research questions, we organized our data according to the three types put forward by Pfannkuch and Horring (2005). Each type generated its corresponding category. Thus, both the research questions and purposes collected were organized into three categories: summary, comparison and relationship. Furthermore, as proposed by Arnold (2013), the first two, summary and comparison, could have been further subdivided according to Arnold (2013) proposal.

## IC analysis: PLAN

In this stage, our data did not allow categories to be established within the *hypothesis formulation component*. Regarding the *data collection instrument*, we observed that all groups used questionnaires with questions that were either open-ended or closed-ended. Thus, we created a first category, format of questionnaire, which is subdivided into three, closed-ended, open-ended or mixed, depending on whether all the questions in the questionnaire were of the first or second type, or a combination of the two. We created a second category, type of questions, which generated two subcategories, sample and aim. In turn, these were further subdivided.

- Sample: included the questions that referred to the population under study:
  - × Characterization: those questions whose purpose was to collect information on the variables that characterized the population under study, such as age or gender.
  - × Selection: questions intended to distinguish between those participants who could provide information to adequately answer the research question and those who could not. “¿Are you currently reading by choice?” (G1) [It did not make sense to ask those who did not currently read willingly to continue answering the questionnaire].
- Aim: included the questions intended to obtain information related to the research topic:
  - × Target: included those aimed at gathering information to answer the research question.
  - × Satellite: included those questions that did not ask for information crucial to the investigation, but which might complement it: “At school, did they motivate your interest in reading? (G10)
  - × Redundant: included those questions that did not contribute anything to the research topic.

## IC analysis: DATA

In this stage of the cycle, we identified two techniques that generated two categories with regard to the *data collection* component: ticking options in a table that anticipated possible answers, and listing answers, copying them as provided by informants. Regarding the component *data cleaning*, we observed that some groups identified and separated the data provided by informants who did not belong to the sample, either visually or non-visually. For instance, in Figure 1, we see how the students separated the answers given by the teacher and the observer by placing them outside the table, since they were not part of the target population.

Pregunta 1

	Has accedit a aquest grau amb 37 / 48 anys?	No far el grau de primària
Sí		(45)

**Figure 1: Visual recording of data provided by informants who did not belong to the sample**

## IC analysis: ANALYSIS

At the outset, we saw that in this stage we had to consider a component previously unspecified in the literature, namely *initial data processing*. Within this component, we observed that the teams either recorded frequencies (absolute and/or relative) of answers to closed-ended questions or constructed categories from the answers to open-ended questions. When the *transnumeration* component (Wild & Pfannkuch, 1999) appeared in the reports, we observed two types of format change which gave rise to the following categories: numerical representations (percentage, centralization measures) and graphical representations (bar graphs, histograms and pie charts).

## IC analysis: CONCLUSIONS

In this stage of the cycle, we constructed two categories related to the *interpretation of results* component: graphical representations and numerical representations, strictly linked to the type of format change of their analysis. To organize our data within the first category, we followed Gea, Arteaga and Cañadas (2017). Thus, we established four subcategories, namely reading the data, reading between data, reading beyond data and reading behind data.

To describe how the written reports that fall into the category of numerical representations reached their conclusions, we looked at two aspects that generated a new category each. The first category, approach, was further subdivided in two, partial and relational, depending on whether the conclusions referred to the numerical results considered one by one, or whether they related the different results obtained, giving more complex answers to the research question.

The second category was related to meaning conveyance and concerned the character of each team's conclusions. It was split into two further categories:

- Descriptive: their conclusions only consisted of showing percentages, absolute frequencies or measures of centralization, without any further interpretation: "Question 3: of the 69 persons surveyed, 73.9% prefer to study on their own, 18.8% choose to study with another person." (G34).
- Interpretative: their conclusions were interpreted in relationship with different elements:
  - × Context: they interpreted their results by integrating information about the context. "We think that this low percentage could be caused by the rise of new technologies, compulsory reads in primary and secondary school, and the little free time available." (G1)
  - × New information: when interpreting their results, they incorporated new information encountered during data collection "We have observed that younger people start drinking alcohol at a younger age, while older people took longer to try it." (G18)
  - × Beliefs: they interpreted their results on the basis of their own beliefs. "We believe this may be due to a change in mentality. A pet is no longer seen as a toy but as a responsibility." (G3) Since the team's results showed that 85% of the surveyed people had had a pet at some point, and 50% of the surveyed population currently owned a pet, this unit of meaning would also be an example of the relational category.

Finally, for what refers to the *relationship between conclusions and the research question* component, several categories arose depending on whether the conclusions answered, partially

answered or did not answer the initial research question or purpose, thus allowing the teams to complete or not the IC. Regarding the *critical reflection* of their process, we observed that they identified strengths and weaknesses, focusing their criticism essentially on the data collection tool they had constructed. Some teams also made suggestions for improvements to their own IC.

## Results

For the purposes of this paper, we are neither interested here in determining how many groups there were in each category, nor in characterizing the work of the different groups, but rather in highlighting the categories as a set. Thus, our main result is a category system that refines, consolidates and broadens the characteristics appearing in the literature. We note the inclusion of two new components: in Stage 4, *initial processing of data*, and in Stage 5, *criticism of their own work process*. Table 1 shows the new study categories on a grey background.

Components	Categories				
Stage 1: PROBLEM					
Capture the dynamics of the context	Rationale	Relevance			
		Curiosity			
		Unspecified interest			
Problem definition	Focus				
	Purpose		Nature	Statistical	
			Non-statistical		
	Research question		Type	Summary	
				Comparison	
				Relationship	
Stage 2: PLAN					
Hypothesis formulation					
Data collection instrument	Format	Closed-ended			
		Open-ended			
		Mixed			
	Type of question	Sample		Characterization	
				Selection	
		Aim			Target
					Satellite
					Redundant
Stage 3: DATA					
Data collection	Techniques	Ticking options			
		Copying answers			
Data cleaning	Visual				
	Non-visual				

Stage 4: ANALYSIS				
Initial processing of data	Frequency records			
	Category construction			
Transnumeration	Numerical representation			
	Graphical representation			
Stage 5: CONCLUSIONS				
Interpretation of results	Graphical representation	Reading data		
		Reading between the data		
		Reading beyond data		
		Reading behind data		
	Numerical representation	Approach	Partial	
			Relational	
		Meaning conveyance	Descriptive	
			Interpretative	Context
				New information
				Beliefs
Conclusions and RQ	Answer			
	Partially			
	Did not answer			
Criticism of their own work process	Strengths			
	Weaknesses			
	Suggestions for improvement			

Table 1: Categories system

## Conclusions

An IC requires having and applying statistical knowledge, completing its stages and thinking statistically. It is a complete structure and we found it useful for the description of the statistical knowledge activated by future teachers when they face a task that reflects an IC. In this paper, we present the creation of a system of categories of analysis based on existing theory and the data we collected, consisting of the written reports of a group of pre-service teachers.

In the process of generating categories we observed the same phenomenon as Wild and Pfannkuch (1999) in the sense that “The thinker operates in all four dimensions at once” (Wild & Pfannkuch, 1999, p. 225). Our proposed analysis revolves around the first dimension, but to interpret our data we need the support of the other three. Thus, the idea of transnumeration included in the second dimension is key to our interpretation of the analysis stage. Likewise, the idea of integration of context, statistical knowledge, and information on the data, is essential if we are to interpret the conclusion stage. Similarly, the stage of searching for information and ideas and the stage of criticizing and judging, both part of the third dimension, are linked to the generation of categories, within data collection and interpretation of results respectively. Likewise, the fourth dimension,

which involves dispositions, is key to the criticism of the teams' own work processes, a new component that emerged from our analysis.

As far as our new system of categories is concerned, we would like to point out that it is not a closed object, since it can be modified or expanded to analyze data obtained from other groups of students (at this and other educational levels) when constructing their own investigative cycles. Furthermore, the subcategories should include the knowledge and processes that we would like our students to have at their disposal as teachers. Meanwhile, the categories may already be useful to researchers when approaching the characterization of statistical knowledge and to teacher educators when identifying their student-teachers' starting point and interpreting their responses.

This research was carried out with the support of research grants EDU2013-4683-R and EDU2017-84427-R –Spanish Ministry of Science, Innovation and Universities.

## Introduction, theoretical background

Inferential statistics is not part of the secondary school curriculum in Hungary. The current plans to reform the national curriculum include the introduction of basic inferential statistics. A working group of the Hungarian Academy of Sciences, of which these authors are members, is exploring possibilities and designing tasks and feasible learning paths. Descriptive statistics – though mainly from a didactical rather than a mathematical point of view – is taught in teachers' education since the early 2000s, while teachers learn basic probability at the university since 1959. Because of this lack in teachers' background, the aim of the project is to design an acceptable way of introducing inferential statistics in high-school curricula both for students *and* their teachers.

This paper is linked to the project „Complex Mathematics Education”. Our work is based on the ideas about teaching probability and statistics of T. Varga and T. Nemetz. We have designed several experiments and tested them by one of the authors (Jánvári) in Szerb Antal Secondary School (grade 11, 17 year-old students). The experiments are determined by their fit into our theoretical views on modelling probability and to the approach of teaching classical and Bayesian statistics together developing the concepts in parallel (Vancsó, 2009; 2018). In these studies, teacher's and students' beliefs and skills were developed by a “parallel course”, which helped to understand classical *and* Bayesian ideas. While the *informal* approaches to teaching *inference* in Garfield and Ben-Zvi (2008) focus on simplifying statistical inference by re-randomisation and Bootstrap, we try to make inference more understandable by integrating the Bayesian view. This is in line with Borovcnik (2017), who describes shortcomings of *informal inference*. It also fits to an analysis of statistical inference from the statistician's perspective by Vic Barnett, which is summarised in a comparative educational study of statistical inference by Borovcnik (2013).

## Conclusion and results

Our first experiment is rolling dice judging whether the die used is well-balanced or loaded by a probability statement. Though this method was introduced in earlier papers (e.g., Lawton, 2009; Dambolena, Eriksen, & Kopcsó, 2009), our approach places greater emphasis on the hands-on in-class experiment. It is used to introduce hypothesis testing. In this case, the Bayesian way is technically too complicated but becomes manageable through the use of software. The second example is a reaction test using a stopwatch. This interactive game among students unfolds connections between different school subjects such as physics, biology, and mathematics. Furthermore, it is also suitable to discuss about discrete and continuous quantities. It is our goal to

use more games in teaching, which is motivating for students and provides an excellent opportunity to discuss basic notions and misconceptions in probability and statistics. Also, application of modern ICT tools in itself can be interesting and challenging for secondary-school students. Moreover, the gamification element (see Papp, 2017) can increase their involvement and consequently their motivation and understanding of the scientific material.

This paper was supported by the Hungarian Academy of Sciences' "The Complex Mathematics Education Project".

### Introduction

The thematic working group 6 (TWG6) in CERME focuses on the research field of teaching and learning mathematical modelling and applications at various educational levels ranging from primary to tertiary education, including vocational courses. The working group also addresses initial and continuing teacher education, where an increasing number of contributions have been offered. TWG6 started at the fourth ERME Congress (CERME 4) in 2005 and it has, since then, continued to be an active thematic working group in the eight meetings through to CERME 11. In total the working group has produced and presented 161 papers and posters.

In its discussions at CERME 11, the thematic working group TWG6 on applications and modelling aimed to seek answers to some open questions in the research field (Schukajlow, Kaiser, & Stillman, 2018), and continue to advance the work from previous ERME conferences. The contributions discussed at the congress are characterized by a strong and fruitful diversity in the research questions considered, the school levels addressed and the theoretical approaches taken. On the whole, TWG6 received 41 papers and posters from 17 countries—most of them from Europe, but also from South and Central America, Iran, South Africa, South Korea and Japan. Finally, a total of 21 papers and 7 posters were presented in the conference, with a total of 40 participants from 14 countries. The next table summarizes the evolution of papers and poster presented in TWG6 in the different CERMEs.

**Table 1: Evolution of the papers and posters presented in TWG6**

In the seven TWG sessions the different papers were discussed organized around five leading themes, which were established after reading and revision of the submitted proposals. Although some of the papers cover more than one of the identified leading themes, the proximity to other research papers facilitated their distribution among the various themes (Table 1).

<i>Leading themes</i>	<i>Papers</i>
T1. Analysis of modelling processes when solving modelling problems	3
T2. Mathematical modelling and simulations in connection to other disciplines	3
T3. Strategies to support design and implementation of modelling	4
T4. Use of resources to support teaching and learning of modelling	2
T5. Teacher education for modelling and its application	9

**Table 2: Leading themes defined and papers assigned in each**

As a first important leading theme papers focusing on creating and testing tools for the analysis of the modelling processes that are carried out when students solve modelling problems were identified. These research papers aimed to elaborate specific tools and methodologies for analysing and evaluating modelling practices. The second theme focused on the interplay and connections between mathematical modelling and other subjects, especially in engineering teaching. The third theme addressed different strategies to support the teaching and learning of mathematical modelling; this includes strategies to foster students work on modelling problems, ways in which teachers can guide their implementation and evaluation as well as ideas regarding the design of modelling activities by researchers (and/or teachers). The fourth theme focused on the use of experimental materials and technology in modelling, and covered two topics: the first primarily focused on the role of the auxiliary material and its impact on the modelling activity and a second concerned with how to combine different resources with technology in concept development by means of real word contexts. Finally, the fifth theme covered teacher education for modelling and its applications. As this theme had a lot of contributions, we organized the contributions into two sub-topics. The first topic was about assessing and measuring teaching competencies for mathematical modelling. The second focused on several instructional proposals for prospective and in-service teacher education for modelling and applications.

## Leading themes and overarching questions

### Analysis of modelling processes when solving modelling problems

This first theme focused on proposing tools and methodologies to analyse the modelling processes individuals or groups of individuals engage in when solving modelling problems. Firstly, *Ärlebäck* and *Albarracín* investigated the potential of extended Model Activity Diagrams as an analytical tool for analysing students' modelling processes by including a sub-division of the modelling tasks at hand in terms of the sub-problems that students work on. Secondly, the paper of *Montejo* and *Fernandez* considered the conceptualisation of the notion of model/s. Based on their analysis of a diversity of definitions about what a model is, according to the educational research literature, the authors introduce a conceptualisation of the notion of model/s as a triplet system-mathematization-representation, and propose for this to be used in future research. Lastly, *Moutet* uses the theoretical framework of the Mathematical Working Space (MWS) to extend the notion of the modelling cycle and to analyse the tasks associated with certain stages of a modelling task in physics, in particular concerning special relativity. This research intends to show how the extended MWS offers a tool for the analysis of the mobilization of the epistemological planes of physics and mathematics and how it relates to the cognitive plane. Although the discussions of the three papers partly focused on different aspects, the following common and overarching questions surfaced in the discussion of the contributions in this first theme:

- § What do these new frameworks (or development of existing ones) add to our understanding of, and our research practices in, the field of teaching and learning of modelling?
- § What are the implications of these frameworks when considering supporting different communities with modelling: students, teachers or modelling task designers, etc.?
- § In what ways can we broaden 'our' perception of what modelling is by comparing different approaches and their interpretation of what modelling is?

### Mathematical modelling and simulations in connection to other disciplines

This theme focuses on the role of modelling and simulations when mathematics is integrated with other disciplines. Some of the papers in this theme touch upon parts of the topic of TWG26 - Mathematics in the Context of STEM Education. However, the aim of the papers in this leading theme is to study the role of mathematical modelling in the context of mathematics education rather than the notion of STEM more generally. Within this thematic strand, we find a diversity of studies, proposals and results that easily connect with other leading themes. The paper by *Poudel*, *Vos* and *Shults* describes an empirical study with students of Development Studies, which aims at introducing examples of real research and methods in social sciences to the students. The authors describe their experience from a university seminar on introducing a research approach to the social sciences with the aim of investigating how students use and gain knowledge about modelling and simulations. *Lantau* and *Bracke* present a study about the use of a STEM-modelling project involving the functional principles of a Segway, within a teacher development programme which later guided their implementation of the STEM-project in secondary school settings (grades 10 to 12). Their aims are to analyse the effective factors and obstacles that teachers manifest concerning the implementation of these modelling activities. In the context of STEM-projects, *Ruzika* and

*Schneider* advocate a multicriteria perspective in relation to mathematical modelling, optimization and decision-making. Their paper presents several examples from real-world problems (including some STEM projects) illustrating the need of multicriteria decision-making and gives some first hints toward incorporating this multicriteria perspective in the teaching paradigm of mathematical modelling. In the general discussion about this theme, we addressed questions such as:

- § How can we facilitate and progress the implementing of interdisciplinary modelling projects given regular school conditions (and not only in the modelling-projects weeks, days, etc.)?
- § What limitations emerge when adapting modelling projects to school and university conditions? What can be done to favour interdisciplinarity modelling projects in schools?
- § What role could or should the other disciplines (natural sciences, social sciences, engineering, etc.) play in mathematical modelling and in mathematical modelling lessons?
- § What new disciplinary and interdisciplinary knowledge needs to be introduced and how do we do this in secondary schools and universities?
- § Can mathematical modelling be considered as a support for the construction and development of inter-disciplinary knowledge? Which constraints do we have to overcome?

### **Strategies to support students and teachers in the design and implementation of modelling**

The papers related to this topic refer to different strategies to support students when solving modelling problems, teachers when guiding their implementation and evaluation as well as researchers (and/or teachers) with the design of modelling activities. The pursued aims are varied, but when organising their complementarities we found some common questions these papers deal with:

- § What strategies do we have (for example: reading strategies and text representations, students' evaluation of given modelling solutions) to help students in modelling? What complementary information can several approaches give us?
- § How can the configuration of modelling activities, or their reconfiguration into different modelling problems, serve different teaching and learning objectives? Which principles for the design of modelling tasks may be established?

Related to the first questions, *Dröse* presents research about the impact of fostering reading and comprehension strategies to support students in successfully solving modelling problems. Through the analysis of some particular case studies with students solving modelling tasks, this research focuses on analysing how certain reading strategies can contribute to different steps in constructing mental text representations, which is an important step in modelling. In their work, *Kuntze* and *Eppler* propose that an effective strategy to support students' modelling practices is to ask students to evaluate some particular given solutions of modelling tasks. In particular, this paper presents some empirical findings relating to secondary students when they review and refine modelling solutions cooperatively in the classroom; the students have to face specific requirements, such as reconstructing modelling thoughts, examining alternative modelling steps and comparing the quality of different modelling solutions.

Concerning the second questions, we discussed two papers dealing with task design issues. *Almeida* and *Carreira* present a theory-based discussion on the configuration of modelling activities to show

how the design of modelling tasks is strongly dependent on the perspective adopted for its implementation. Based on some particular examples, an analysis of the task configuration is carried out in light of the more implicit or explicit aims of mathematical modelling in teaching and their connection with various modelling perspectives. From the examples, it is possible to argue that the configuration of modelling tasks is adaptable, which entails flexibility and reinforces the relevance of an educational standpoint in designing modelling problems. Last but not least, *Pla-Castells* and *Ferrando* describe an empirical study with the objective of designing a sequence of modelling tasks focusing on solving a big number estimation problem. They use the so-called downscaling - upscaling techniques for the design of this particular Fermi problem, which is later used to analyse the implementation with primary school students of second grade (7-8 years old).

### **Use of resources to support teaching and learning of modelling**

This theme focused on the use of different kinds of resources: digital technology, physical resources, etc., at the different stages of the modelling process. In particular, some papers aim to discuss the role of the physical or digital prototypes and of simulations at the different stages of the modelling process. In *Baioa* and *Carreira*, the authors explore and discuss the use of simulations with physical models and prototype constructions in the process of modelling. They choose some examples in the inter-disciplinary context of STEM to analyse the use of prototypes and simulations in students' activity going through the entire mathematical modelling cycle. The paper links to *Lantau* and *Bracke*'s research in their detailed analysis of the potential of combining STEM and mathematical modelling. *Lieban* and *Lavicza* discuss the affordances of using and combining physical and digital resources for exploring geometrical modelling. Within the context of pre-service teacher education, the authors explore the use of physical simulation and digital resources, in particular using Geogebra, to support modelling in the transition between 2D and 3D models construction. These papers also establish connections with the aforementioned paper by *Moutet* on the use of digital technologies to simulate physical phenomena involving special relativity. Some of the matters largely discussed were:

- § How can we conceptualise simulations within mathematical modelling processes? What do simulations change for model building in the different steps of the modelling cycle?
- § How can digital and physical tools change ways of approaching modelling problems? How do they change the meaning of “working mathematically” today?
- § Do we need to rethink the definition and conceptualizations of the steps of the modelling processes when using technology and simulations?

### **Teacher education for modelling and its application**

This last theme is the one that attracted most papers. The topic of teacher education is a valued one within the group, based on the acknowledged need of preparing pre-service and in-service teachers for the teaching of applications and modelling. Papers in this leading theme were organised in two sub-topics to facilitate their discussion. The first topic focussed on assessing and measuring teaching competencies for mathematical modelling. The second topic covered works on the proposal of different teacher education courses for pre-service and in-service teachers of primary and secondary school education.

Concerning the first topic, *Borromeo-Ferri* focuses on the question about how mathematical modelling competencies can be assessed and, more concretely, how to see an increase of teaching competencies after a course on ‘learning and teaching of mathematical modelling’. A test instrument was presented and used to assess modelling competencies for students and teachers participating in several empirical studies at secondary level. In their paper, *Klock* and *Siller* emphasize the importance of providing teachers appropriate ways of supporting students working on modelling processes, in particular, through a precise diagnosis in the intervention process. Based on a process model, another instrument for measuring teaching competencies was presented. Thus, based on the data measured by this instrument, the cause-and-effect relationship between a correct diagnosis and the selection of an adaptive intervention can be analysed. Some of the questions that emerged from the group discussion were:

- § How to ensure that the test instruments for assessing modelling competencies are significant enough, in the sense of sufficiently independent, from the modelling perspective adopted?
- § How can these instruments (assessment, diagnosis, intervention) be useful for teachers’ practice when implementing modelling activities with students?

Closely related to the previous papers, using the conceptualization of the modelling cycle and competencies, and presenting particular instructional proposals we considered several papers. *Wess* and *Greefrath* focus on the modelling-specific task competency of prospective teachers in the teaching laboratory MiRA+. In this laboratory, teachers are encouraged to design their modelling tasks and apply them in practice with emphasis on the acquisition of competency by their students. *Guerrero-Ortiz* present the results developed with prospective mathematics teachers who took part in a seminar with the aim of developing their mathematical and pedagogical content knowledge in the process of designing modelling tasks and discussing about these teaching proposals. Furthermore, *Alwast* and *Vorhölter* discuss the important gap between the theory conveyed at university and the teachers’ practical work at school and how to help future teachers make their knowledge applicable to practice. They use staged video vignettes to simulate real classroom situations and support future teachers episodic memory through repeated practice with these videos.

In their paper, *Yvain-Prébiski* and *Chesnais* identify horizontal mathematization as a crucial component of mathematical modelling. Based on this conceptualization of horizontal modelling, the authors analyse the implementation of a modelling task about the growth of an exotic tree with a large group of secondary school classrooms to analyse how teachers spontaneously manage these initial steps for modelling, especially analysing their difficulties on implementing horizontal mathematization. *Kaneko*, *Saeki* and *Kawakami* aims at creating contact points between empirical modelling and theoretical modelling in teacher education. The authors explore the case of a pendulum modelling problem and the analysis of modelling lessons related to this problem to make teachers reflect on the significance and complementarities between theoretical and empirical modelling.

In her paper, *Jessen* presents a model for upper secondary in-service teacher courses based on the anthropological theory of the didactics and explores how to train teachers to design and implement

mathematical modelling in their classrooms. The course evolves around the proposal of study and research path based teaching and strives to create paradigmatic infrastructures as a framework for collaborative development of teachers' teaching practice. Under the same theoretical approach, *Barquero, Bosch* and *Wozniak* address the problem of the teachers' lack of discursive tools to teach modelling processes and how it can be addressed through teacher education. This paper describes a teacher education course with pre-service primary school teachers where the terminology of modelling and the questions-answers maps are proposed to provide future teachers with a discourse—a logos—to explain and analyse the modelling praxis.

Due to the diversity of research questions and of proposals about teacher education, the discussion was particularly rich. Some of the overarching questions addressed when discussing the papers, were the following:

- § How does the process of designing modelling tasks contribute to improved knowledge about modelling and modelling processes for teachers?
- § How do the course 'elements' impact on the practice of the teachers? What tools are better transferred and adopted by teachers?
- § How can we get information (and/or measurements) about the success of teacher appropriation or adoption of the tools introduced in the instruction?
- § What different formats, of training teachers for modelling, may lead to a stronger integration of modelling in school contexts?
- § Why are we not achieving autonomy amongst in-service teachers with respect to implementing mathematical modelling activities in their classrooms?
- § How can we ensure a long-term collaboration between teacher and researchers in the implementation and analysis of modelling activities in regular school conditions?

## Concluding remarks and perspectives

The leading themes addressed by the TWG6 show the variety of research approaches and questions the papers dealt with (Kaiser & Sriraman, 2006). Furthermore, the educational levels spanned from primary to tertiary education, also covering teacher education and in-service courses. Comparing the papers and approaches considered to the different perspectives described in Carreira, Barquero, Kaiser and Cooper (2019), that summarises the evolution of the group we can conclude that in CERME 11 the research presented covered most of these perspectives.

In the first theme we discussed the use and applicability of specific tools and methodologies for the analysis of students' modelling processes and its evaluation. The modelling cycle (and its variations) has been prominent in the group. But other approaches to modelling were also discussed, such as Model Activity Diagrams, Mathematical Working Space or the one proposed by the anthropological theory of the didactics. The discussions broadened our focus and opened new questions about possible complementarities between different approaches. Furthermore, a question for future research was about how to transform all the analytic tools for analysing students' cognitive processes into tools facilitating the teacher's task of analysing students' modelling processes.

The second theme focused on the role of modelling in connection to other disciplines. More concretely, on the interdisciplinary approach to the teaching of mathematical modelling, in particular in the context of engineering and STEM education. There is a long tradition in TGW6 of discussing examples under this theme, and we hope to continue to attract work that involves consideration of modelling in different interdisciplinary contexts and practitioners enlightening mathematical modelling from perspectives of other disciplines or contexts.

The third theme, more associated with the instructional perspective, argued for different strategies to support the teaching and learning of modelling, in particular, different approaches to support students in solving modelling problems, and teachers in guiding their implementation and in evaluating modelling activities. Related to this, the fourth theme we addressed focused on the use of technology and physical or digital resources in the teaching and learning of modelling. Questions about “how to conceptualise simulations within the modelling process” or “what do we mean by ‘working mathematically’ when using technology and simulation” have been largely discussed. Moreover, open issues for future research arose from the discussion in TWG6 as, for instance, the need for extending research on teacher education for the use of simulations and modelling.

At CERME 11, teachers and their role in teaching modelling as well as teacher education played a prominent role, as more than half of the papers were dealing with prospective and/or in-service teachers. This shift shows a clear further development of the discussions and the work of TWG6, which needs to be fostered and broadened. Teachers and their professional development are crucial for the integration of mathematical modelling into mathematics education at various levels. Some questions remain open for future research about how to evaluate the impact of teacher training on the use of modelling in the classrooms as well as the teachers’ autonomy in doing so.

## Acknowledgment

We want to thank to all the participants of TWG6 at CERME 11 for their presentations and participation on the discussion and working together in the sessions. We had the chance to reflect on the present and future lines of our research on modelling and applications.

## Introduction

Recently, in an article offering a synthesis of the relevant knowledge on the teaching of mathematical modelling, Blum (2015) revisits the main arguments – long-established since the influential ideas of Blum (1991) and of Blum and Niss (1991) – that justify the implementation of mathematical modelling activities in school mathematics. The four main arguments, which can also be seen as aims for the integration of mathematical modelling in mathematics education, are: i) the *pragmatic* argument; ii) the *formative* argument; iii) the *cultural* argument; and iv) the *psychological* argument. The first tells us that we need to use mathematics to understand the real world, so we must learn to model the world mathematically; the second affirms that in solving real problems through modelling we develop fundamental competences; the third argues that without applying mathematics and constructing models we cannot truly get a comprehensive view of mathematics; the fourth claims that mathematical modelling contributes to a better understanding and structuring of mathematical content in mathematics learning. In retrieving those reasonably established arguments, Blum (2015) adds an important note: there is a certain duality embedded in the four arguments; shortly put, one of them points to the value of knowing mathematics for solving real problems; the others consider the value of solving real problems for the learning of mathematics. He also states that examples are needed to advance those different aims in mathematics education and offers several specific contexts and situations that may suit each of them. The examples are in fact essential for several reasons. One is that different examples may fit better with some aims than others; the other reason is that a modelling activity is always based on a task, whether it is a real open problem, a research project, or a more direct question focusing on studying a particular model. In principle, there is no reason why a single basic problem or situation cannot be configured in different alternatives and that it can thus contemplate several aims of mathematical modelling. A mathematical modelling situation has the possibility of being extended, enlarged, or deepened and explored, in many and various ways. This

may be seen in the later work proposed within the models and modelling perspective, in terms of the design of model development sequences (e.g., Ärlebäck, Doerr, & O’Neil, 2013).

A first highlight is that there is a well-recognized plurality of perspectives concerning the educational aims for modelling in mathematics education. In their synthesis of the work developed within the TWG6, at CERME 9, Carreira, Barquero, Kaiser, Lingefjard, and Wake (2015) found clear evidence of a “plurality in the visions and arguments of researchers from different countries about the purposes of including modelling in the mathematics curriculum and in regular classroom activities” (p. 792). A second idea to be underlined is that creating mathematical modelling tasks is about formulating problems, asking questions, generating outbreaks of inquiry and investigation. Moreover, we cannot forget that the formulation of problems based on real or realistic situations is something that can be done by both teachers and students, autonomously or collectively.

Keeping in mind these general ideas, our purpose is to capture how the configuration of modelling activities or their reconfiguration into different modelling problems may serve different teaching and learning aims. This motivates our reflection on the adaptable configuration of tasks from the point of view of the perspective of modelling that drives the teaching and learning practices.

### **Principles in the design of modelling tasks and their relation to educational aims**

Some important progress has been made on developing criteria to guide the design of mathematical modelling tasks for educational contexts. Such work may be found, among others, in the contributions of Bock, Bracke and Kreckler (2015); Borromeo Ferri (2018); Leiss, Schukajlow, Blum, Messner and Pekrun (2010); or Maaß (2010).

Maaß (2010) developed a taxonomic model for modelling tasks. According to her proposal, the aims for the integration of modelling into mathematics classes are numerous and diverse and can be linked to different educational perspectives. In her words, “the objectives are not to be viewed as characteristics of modelling tasks but as criteria for their selection” (p. 289).

The work of Czocher (2017) relates the task design to specific features that incite going through the steps and processes established by the generally accepted modelling cycle. The idea that the choice and design of tasks involve decisions that are not made in a vacuum is here reinforced: “How the tasks are intended to be used should be a determining factor in their design” (p. 138).

In an action-research project involving curricular integration and classroom practice of modelling in pre-calculus classes, Buhrman (2017) formulates a broad research question: “How does a teacher design and enact authentic modeling tasks in a diverse secondary mathematics classroom?” (p. 45). Buhrman presents a rich and systematic account of the many decisions and educational aims that she dealt with in designing and refining the tasks proposed to the students.

Geiger (2017) explores guidelines for modelling tasks that reflect the availability of digital technologies and its integration in the process of mathematical modelling. Within a teachers-researchers collaborative project, the author shows the result of putting the role of digital tools to the fore in the design of modelling tasks. The fundamental role of educational aims in the design of tasks is also acknowledged: “task selection, adaptation, and creation are intertwined with choices of pedagogies for realising opportunities that lie within specific tasks” (p. 289).

The enlightening work of Borromeo Ferri (2018) also speaks about the fact that it is not trivial to design a good modelling problem and suggests that good tasks are generally linked to instructional quality: “task competency is necessary for teaching modeling in all grades. Furthermore task competency leads you to instructional flexibility” (p. 42).

## Perspectives on the integration of modelling and applications

A well-known differentiation of modelling perspectives, according to their central aims in connection with modelling, was proposed by Kaiser and Sriraman (2006). Blum (2015) suggests a slightly different classification, although essentially both can be seen in a similar way, as we suggest in Table 1. Blum’s proposal, however, emphasizes some interesting aspects related to the kind of tasks that tend to be dominant or privileged by each perspective. In his view, a modelling perspective could be formally characterised by the pair: aim – suitable examples. His idea of the aim-task association provides a simple way to imprint the core of each perspective as a form of its identification. Having in mind that both classifications seek to bring out the most distinctive aspects of each perspective, it will be likely that many different aims can fit into more than one perspective. Activities and their different configurations are not good or bad *per se*; it depends on their purpose (Blum, 2015). This suggests that flexibility and craftwork are crucial in the configuration of modelling activities in the educational context (Borromeo Ferri, 2018; Buhrman, 2017).

**Table 1: Brief outline of modelling perspectives**

Perspectives (Kaiser & Sriraman, 2006)	Perspectives (Blum, 2015)	Aim   Task
Realistic	Applied	pragmatic   authentic
Didactical	Educational	formative   cognitively rich
Socio-critical	Socio-critical	cultural and emancipatory   authentic
Epistemological	Epistemological	cultural concerning mathematics   epistemologically rich
Contextual	Pedagogical	Psychological, marketing intention   motivating
Conceptual	Conceptual	psychological   mathematically rich

## Multiple configurations of modelling activities

We then present two examples of modelling tasks or problems that allow us to realise the adaptable configurations of modelling tasks for teaching. In the first, we chose a particular starting situation regarding the world economic inequality and elaborate on that, in view of different modelling perspectives. In the second, we show how students independently formulate problems, inquire and develop mathematical modelling guided by purposes that are connected to the pragmatic solution of a real problem that is relevant to them.

### Diverse configurations aligned with modelling perspectives

The first activity – world wealth distribution – was developed in a class of 20 students, divided into 4 groups, in a course of Mathematical Modelling for pre-service mathematics teachers, in a Brazilian university. In this activity the image shown in Figure 1, along with a report on the explosion of inequality in the world, published by the Brazilian magazine *Exame*, on January 19, 2015, was delivered to the students<sup>1</sup>. The report draws attention to the fact that inequality has increased in the

<sup>1</sup> Available at <https://exame.abril.com.br/economia/4-graficos-que-mostram-a-explosao-da-desigualdade-no-mundo/>

period from 2000 to 2014. According to the report, the distribution of global wealth is striking when one compares the wealth share of the world's 1% richest people to the wealth share of the other 99% of the population. The aims underlying the configuration of the activity concerned the development of students' ability to mathematize a situation (the distribution of wealth) and to obtain answers to a question arising from it. Thus, the students would have to define strategies to answer the question and, in this case, those strategies should prioritize mainly the 'how to' use mathematics to achieve a prediction.

Figure 1: Share of global wealth of the top 1% and bottom 99% respectively; Credit Suisse data available 2000–2014.

Figure 1: Curves of economic inequality

Based on the impression that the two curves will intercept in some year after 2014, assuming “business as usual”, can we say in which year the wealth of the richest 1% equals the wealth of the other 99% of the population?

### Configuration A (Didactical modelling)

Based on the impression that the two curves will intercept in some year after 2014, assuming “business as usual”, can we say in which year the wealth of the richest 1% equals the wealth of the other 99% of the population?

With this configuration, the activity seems to be in line with what Kaiser and Sriraman (2006) characterize as the “didactical perspective” of modelling. In this case, the focus was the process of solving the problem rather than the mathematics content itself. The purpose of the mathematization was to predict a future event.

We refer here to the work of two groups of students (G1 and G2) who decided to tackle the problem situation by means of using the software GeoGebra, which was already familiar to them. The students from both groups started their work by inserting the image in the GeoGebra graphics view and created points on the curves for successive years (Figure 2).

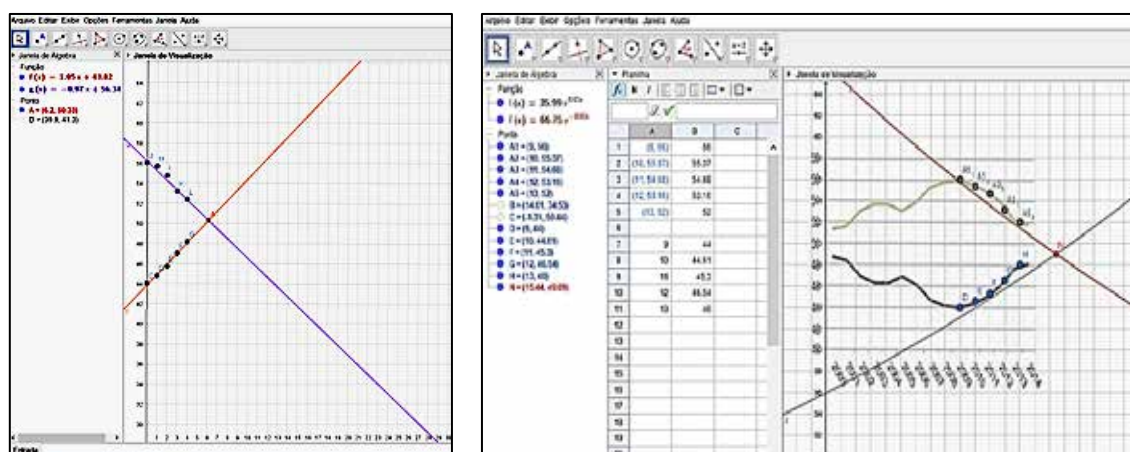

Figure 2: (Left) Linear model from group G1 and (Right) exponential model from group G2

Considering that their goal was to use the data from the picture to make predictions after the year 2014, the students considered the points relative to the years 2009–2014. Using the spreadsheet view and the bivariate regression analysis tool in GeoGebra, students in G1 selected a linear regression model to determine the predicted growth of the richest as well as the poorest shares (Figure 2, left). On the other hand, students in G2 opted by exponential regression models (Figure 2, right). Although

the two groups have adjusted different models, both concluded that after the year 2016 the wealth of the richest 1% already surpasses that of the other 99% of the world population.

Starting from the given situation, other configurations, involving the design of other modelling problems, may be produced, in line with other educational aims and modelling perspectives. Next, we refer to two of such variations. In the second configuration, which is in line with “conceptual modelling”, one aim is the eliciting of models leading to concepts such as Riemann sums and the average value of a function over an interval. The affordances of GeoGebra would also be relevant, namely by interconnecting the graphic window and the spreadsheet window. Many explorations would be feasible in that approach; in fact, another aim could be the integration of technology in the modelling process.

### *Configuration B (Conceptual modelling)*

Based on the data from the graph what could you say about the average gap between the shares captured by the top 1% and the bottom 99%, between 2000 and 2014? According to your approximate model reflecting the trend, how will this gap change over the following 14 years?

In the third configuration, the emphasis is on critically reflect on the world inequality portrayed by the 2016 situation, where the top 1% of the population captures half of the world wealth. Here, in line with a “socio-cultural perspective” the objective concerns the use of mathematics to unveil social and political phenomena and promote informed critical positioning. The need to produce a good representation of a clearly asymmetric distribution will require creative thinking. Either the students look for information about the values of the percentiles for 2016 or they may run a simulation that generates 100 numbers (where one number is 50 and the sum of the all the others is also 50). The usefulness of mathematical representations is intended to be a topic of deliberation. But mostly, reflective and critical examination of the real world by means of mathematics is a fundamental implicit aim in this task configuration.

### *Configuration C (Socio-critical modelling)*

A student responsible for the newsletter of his school/faculty wonders about how to depict the current distribution of wealth among the world population, in an article about economic inequality. What would be a good mathematical representation of the distribution that people would easily understand?

Write a boxout text (half page) to accompany the student’s article where you show your representation of the wealth distribution, indicating the source of your data and explaining the fundamental ideas that may be drawn from it. Remember that boxouts are intended to be visually interesting and have condensed information. They should incite the reader to think and to know more on the subject.

### **A task configuration serving different perspectives**

In the following example, unlike the previous one, the teacher did not present a modelling problem to the class of pre-service student-teachers. Instead, each group of students was asked to choose a real situation to investigate and create a modelling problem that should be solved. One group of students used to fish in a Fish & Pay Lake and became interested in studying the potential profit that the use of tilapia leather could provide to the owner of the pond.

First, the students thought about how to measure the amount of leather obtained from each fish. For that end, they caught fishes with weights varying between 280g and 720g. To determine the surface of the leather of each fish they used an approximation by means of triangles (Figure 3). They recorded the measures of the sides as well as the area of each triangle, by applying Heron's formula and using the Excel software. From there, they sought to relate the weight and surface of the fish. They defined the variables:  $x(t)$  as the weight (in grams) of a tilapia aged  $t$  weeks and  $y(t)$  as the tilapia leather useful area (in  $\text{cm}^2$ ) after  $t$  weeks. The growth rates of these two properties of the fish in relation to time are, respectively,  $\frac{dx}{dt}$  and  $\frac{dy}{dt}$ . To relate the surface to the weight, the students used the Allometry

**Figure 3: Approximation by triangles**

Principle, according to which one has  $\frac{1}{y} \frac{dy}{dt} = k \frac{1}{x} \frac{dx}{dt}$ , where  $k$  is a constant. By solving the differential equation, they arrived at the solution:  $y = cx^k$ . Finally, the students resorted to their spreadsheet table and used Excel for getting the best fitting curve:  $y(x) = 2.165x^{0.751}$ .

To consider the issue of the revenue from the sale of the tilapia leather, the students talked to the staff in charge of the fisheries and learnt that the average weight of the caught fish is 500 grams. So they applied their model:  $y(500) \approx 230 \text{ cm}^2 = 0.023 \text{ m}^2$ . Taking into account that 2.5 tons of fish are sold per month, that the average weight of each fish is 500 grams, that the price of a square meter of leather is R\$ 6.00, and that each fish provides approximately  $0.023 \text{ m}^2$  of leather, the students concluded that the owner could earn R\$ 8,280 per year from the tilapia leather.

The configuration of this activity indicates that the aims of the teacher and those of the students can be different and complementary when modelling activities are carried out.

#### *Configuration D (Applied modelling and Contextual modelling)*

Teacher's configuration: Formulate a real problem of your choice, connected to the real world and life, and use mathematical modelling to solve it.

Students' configuration: What is the potential profit that the use of tilapia leather could provide to the owner of the pond where I often go fishing?

The teacher is interested in giving students the opportunity to engage in an investigative activity and encourages their autonomy in finding authentic situations where mathematics could be useful and valuable. As such, the students formulated a problem stemming from their interest and curiosity, looked for the available mathematics to model the situation, and found a solution, which is in line with the "applied/realistic perspective". One important aim for the teacher is the students' learning and experience of the mathematical modelling process; for the students, the aim is formulating a real world problem, which they can solve through mathematical modelling. In fact, part of the students' modelling process involved applying relevant models they had available, such as the Heron formula and the Allometric model. In this sense, the task also led students to activate and apply their

mathematical and extra-mathematical knowledge to a real situation, and therefore it may be considered to be aligned with the “contextual perspective”.

## Concluding remarks

The discussion on the nature and design of mathematical modelling tasks for diverse educational and curriculum contexts is worth continuing. Not because the tasks decide in any absolute way the results that will be achieved with the students, but because they constitute a recognized central element of the pedagogical practices (Borromeo Ferri, 2018). In particular, the tasks reflect, to a large extent, the centrality of the teaching and learning aims. In embracing this idea, we have looked at two very distinct types of modelling tasks proposed by the teacher to undergraduate students in a university course in mathematical modelling for teaching. In one of them, we explored variations in the outline and the target of the task, keeping in the background the same real situation concerning the evolution over the years of economic inequality in the world today. We have suggested possibilities to make the task coupled with different aims of teaching and learning, which implied, in particular, to formulate relevant questions that direct the activity to different targets: didactic aspects regarding the search for suitable models to predict results (e.g., the use of graphic tools and curve fitting to develop models); conceptual development (e.g. introducing or developing mathematical concepts); or reflexive and critical understanding (e.g., using mathematics to unveil and raise awareness of social phenomena). We have also made its connection with different perspectives of modelling, echoing, in some way, an idea previously proposed by Kaiser, Sriraman, Blomhøj, and Garcia (2007), about a situation concerning the structure of the price of a taxi. This allowed elucidating the degree of adaptability of good modelling tasks to various configurations and that means that the configuration of modelling activities is part of the teacher’s role that implies her/his positioning in some perspective, more or less explicitly. Afterwards, we looked at another modelling task configuration in which the teacher proposes the search for a real situation that may be interesting to study from a mathematical point of view; thus, the teacher invites the student to investigate the world around and to identify a problem that is both relevant and possible to analyse through mathematics; the teacher expects the students to formulate problems and to go through the modelling cycle in their modelling process. Drawing on the case of a group of students we have shown how the students’ inquiring attitude entails other aims that are equally relevant and aligned with a realistic perspective, since the students adopt a position similar to the applied mathematician. The diverse aims involved are complementary and reveal that some configurations can actually serve different modelling perspectives.

The examples reveal that the design and choice of tasks are intertwined with different aims and perspectives of mathematical modelling for mathematics education. Our reflection reinforces the idea of flexibility, emphasized by Borromeo Ferri (2018), but it also highlights the relevance of taking an educational standpoint in designing modelling problems.

# Enhancing future teachers' situation-specific modelling competencies by using staged videos

Alina Alwast<sup>1</sup> and Katrin Vorhölter<sup>2</sup>

<sup>1</sup>University of Hamburg, Germany; alina.alwast@uni-hamburg.de

<sup>2</sup>University of Hamburg, Germany; katrin.vorhoelter@uni-hamburg.de

*Although discussed frequently, there is still a gap between theory conveyed at university and the teachers' practical work at school after finishing their degree, which can lead to the problem that new teachers do not act based on theoretical constructs although they know about them. The paper describes an innovative project, which aims at tackling this problem and fostering teachers' situation-specific competencies by helping future teachers making their knowledge applicable. Therefore, staged video vignettes are created to support future teachers episodic memory through repeated practice with videos, which simulate real classroom situations. This theoretically informed paper focuses on identifying criteria for staged video vignettes based on the concept of teacher's expertise in mathematical modelling, using those when creating video vignettes and implementing them in an innovative learning environment.*

**Keywords:** *Mathematical modelling, teachers' situation-specific competencies, teachers' expertise, video vignettes, staged videos.*

## Introduction

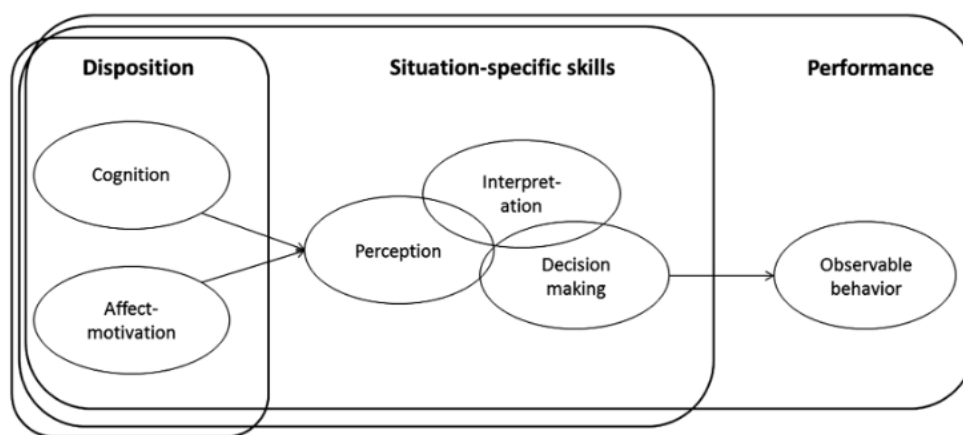

In the last decade a great number of small-scale as well as a few large-scale studies in the field of mathematics education have focused on teachers' expertise (e.g., large-scale studies: TEDS-M, see Blömeke, Kaiser, & Lehmann, 2010; COACTIV, see Kunter, Baumert, & Blum, 2011). These studies focus on conceptualizing the teacher's knowledge and observe their performance in comparison. However, there exists a gap between knowledge and performance, which is addressed by Blömeke, Gustafsson, and Shavelson (2015) in their PID-model. Their conception of competence as a continuum consisting of dispositions (knowledge and an affective-motivational component), situation-specific competencies and performance suggest a greater relevance of situation-specific skills for the teaching profession. In an innovative project at the University of Hamburg these situation-specific skills are enhanced by the intensive use of videos during a master seminar for future teachers, which deals with the content of mathematical modelling. This paper will describe the development of criteria for staged video vignettes in a theoretically informed approach and the usage of the thereby developed video vignettes during a modelling seminar.

## Teachers' professional competencies

As mentioned above this project especially pays attention to the situation-specific competencies as a mean to bridge the gap between theory and practice. A close connection of theory and practice according to the concept of *practice transfer* is aimed at through the analysis of video vignettes. Prenzel (2010) defines transfer (based on studies by Messner, 1978 & Renkl, 1996) as the implementation of a solution developed or knowledge acquired in situation A to another situation B. Effectively solving the problem in situation B means the transfer was successful. Nölle (2002) suggests that professional competence can only be improved through broad knowledge as a basis but

also through episodic experiences. Apparently, a categorical system of knowledge combined with episodic elements is required for the useful application of knowledge and favours a differentiated perception of teaching (Nölle, 2002).

A model, which covers all aspects of teachers' expertise, namely knowledge as well as the skills needed to transfer knowledge into action (called situation-specific skills<sup>1</sup>) and the observable behaviour, was developed by Blömeke et al. (2015). The so-called PID-model (see Figure 1) combines the analytic view on teachers' competencies, which analyses teachers' dispositions in all its aspects (knowledge and affective-motivational components), with the holistic view, which focuses on the teacher's performance. The situation-specific skills serve as a link between dispositions and performance and can be distinguished in the professional perception of a teaching situation, the interpretation of the perceived situation and the decisions made, which are based on the interpretation. For this project, the PID-model is used as a theoretical basis.

**Figure 1: Competence as a continuum (Blömeke, Gustafsson, Shavelson, 2015, p. 7)**

The PID-model describes general teaching competencies but can be applied to specific domains as well. However, in every domain certain knowledge and concepts are required. For teaching mathematical modelling specifically, there exists little research on what exactly is needed to foster students' modelling competencies. Mathematical modelling is a complex task for students, because it demands a lot of cognitive work. Thus, supporting students during their modelling process is also a major challenge (Blum, 2011).

Borromeo Ferri and Blum (2010) developed a model, in which they divided teacher's pedagogical content knowledge (PCK) regarding modelling in four dimensions:

- (1) a theoretical dimension (incl. modelling cycles or aims and perspectives of modelling as background knowledge),
- (2) a task dimension (incl. multiple solutions or cognitive analyses of modelling tasks),
- (3) an instructional dimension (incl. interventions, support and feedback), and
- (4) a diagnostic dimension (incl. recognising students' difficulties and mistakes). (Blum, 2015, p. 89)

<sup>1</sup> The ability to notice and interpret remarkable situations in the classroom is also known as *professional vision* (cf. among others Goodwin (1994) or Seidel and Stürmer (2014)) or as *noticing* (cf. Van Es & Sherin (2002)).

Blum (2015) also highlights that a transfer from knowledge into actions cannot be expected automatically. Supporting teachers in applying their knowledge, which is based on Borromeo Ferri and Blum's four dimensions, is therefore an important aim of this project.

Furthermore, Blum (2015) summarizes ten important characteristics for adequately teaching mathematical modelling based on the concepts of quality mathematics teaching. Besides the principles named above, he mentions an "effective and learner-oriented classroom management", providing a variety of examples and exercises for different real-world and mathematical contexts, encouraging multiple solutions, supporting students' positive beliefs and attitudes towards modelling and using digital tools as an aid.

Moreover, in a study evaluating the modelling seminar university students mention the importance of interventions and the wish to deepen their knowledge and practical skills in this area (Vorhölter, 2018b). As shown in various studies, a crucial tool in supporting students are strategic interventions, which are already mentioned in Borromeo Ferri and Blum's third dimension as PCK. In his study with a focus on the procedural aspect Leiß (2007) points out the importance of strategic interventions to support students' independent modelling process. Stender and Kaiser (2015) discover similar findings adding that strategic interventions can only take place if the teacher is trained in this special field. This is based on the Zech (2002) taxonomy of assistance, which categorizes interventions from minimal help such as motivational interventions to content-related interventions.

Besides, enhancing students' metacognitive-strategies is essential as shown by various studies (for an overview see Stillman, 2011). Metacognitive strategies are needed to independently overcome problems during the modelling process and a lack of these will most probably lead to considerable problems (Vorhölter & Kaiser, 2016). Therefore, teachers need to promote cognitive but also metacognitive strategies.

For overcoming the gap between theory and practice, staged videos can be used during teacher education. According to Oser, Heinzer and Salzmann (2010) videos are situation-specific, authentic, complex and context-bound, which makes them the closest tool to imitate real classroom situations. Thus, the substantive aspect of construct validity (Messick, 1995), which is defined as measuring the cognitive processes of competence as close as possible to the theoretical construct, is met. In a meta-analysis of studies regarding the use of videos in teacher education Coles (2014) summarizes that positive effects can be found when "engaging in a process that makes evaluative discourse unlikely" (Coles, 2014, p. 271). Therefore, it is important to explicitly focus on details and their interpretation when watching video clips in contrast to judging the behaviour of students and teachers in the video.

## **Concept of the modelling seminar**

The University of Hamburg offers a modelling seminar during the master's program - usually attended in the first semester-, which every future mathematics teacher gets the chance to attend. The seminar is open for future teachers of primary and secondary school as well as special-needs school and about 30 students attend it every year. Supervising year 9 students during a two-day modelling project is part of the seminar, which aims at enabling future teachers to independently and adequately teach modelling at school in their future job.

The content of the seminar follows the model by Borromeo Ferri and Blum (2010) and can therefore be divided into four aspects:

1. The *theoretic dimension* is implemented by reflecting and discussing articles regarding the following topics: modelling cycles, goals and perspectives of modelling, students' modelling competencies, beliefs and both heuristic and metacognitive strategies. With different methods knowledge about these topics is gained and practiced using worked examples by school students.
2. To acquire knowledge in the *task dimension* the university students have to solve complex modelling tasks themselves and discuss the appropriateness of different solutions including the three tasks they have to supervise during the modelling days. Furthermore, modelling tasks are analysed concerning their demands and difficulties.
3. The *instructional dimension* is discussed by planning the modelling days, e.g. preparing and reflecting the structure, the introductory phase and especially appropriate interventions, which support independent student work.
4. To address the diagnostic dimension, the university students analyse past students' posters presenting their work and identify difficulties and obstacles.

The seminar concludes with the modelling days at school, where the gained knowledge can be implemented and reflected on. Usually the future teachers work in a tandem to discuss each other's performance and reflect on the success of their interventions (for a detailed description of the modelling days and the role of the university students' see Stender and Kaiser (2015)).

Besides providing declarative knowledge, not only relevant for teaching mathematical modelling but also for other domains in mathematics education, a major focus is the transfer from theory to practice. Due to the university's structure, the future teachers usually do not have hands-on experience with teaching when joining the seminar. Therefore, to support the application of knowledge, videos are used as an import tool to simulate real classroom situations, which will be further discussed in the next section. For a more detailed description of the modelling seminar, see Vorhölter (2018b). The transition between theory and praxis is an ongoing process including knowing theoretical constructs, implementing them and reflecting on experience to deepen those theoretical constructs. Group discussions during the seminar regarding university students' video analyses as well as self-reflections on the modelling days in the context of a final assessment also allow them to refer empirical knowledge back to theoretical constructs.

## Developing criteria for staged videos

A previous evaluation of the modelling seminar shows that the theoretical knowledge was not perceived as relevant for the university students when teaching at school and could not be translated into practical and usable knowledge in a satisfactory manner (Vorhölter, 2018b). To help them make their knowledge applicable videos will be used as stimulation of the reality. As video recordings usually contain distracting background noises, show long stretches of irrelevant behaviour and sometimes do not catch the students' material or facial expressions, we aim at creating staged videos based on authentic situations found in the original recordings.

To create videos, which show typical situations during a modelling process relevant for future teachers on the one hand, but also limit the amount of irrelevant and time-consuming information on the other hand, a cyclic process characterized by various revisions took place. First, recorded lessons were used to identify relevant situations. These were developed during the project MEMO (Vorhölter, 2018a), which includes 2 fully recorded lessons of over 50 small groups of students each time, in

which mathematical modelling takes place. Only a few of the original recordings could be used due to their length and the great number of distractors.

Therefore, a script was written based on teachers' required modelling competencies and students' typical mistakes regarding modelling. These aspects were identified based on the theoretical construct of teacher expertise in modelling. The script empathizes relevant aspects in order to make them noticeable without being in the context of the lesson in real-time. Important aspects were:

1. Each video shows a different *phase of the modelling cycle*, which can be expected to be recognized. Different phases generate different problems and are therefore crucial for a diagnosis.
2. Because modelling is a cognitive demanding task, it can lead to *various difficulties and obstacles*, which can be mathematical, group work related, concerning the modelling process in general and so forth. The video vignettes try to address a wide range of these problems.
3. To tackle these problems, sometimes the teacher has to intervene. *Interventions* are part of the video vignettes as well as the request for the viewer to describe his or her own intervention as if he or she were there to support the students during a difficult situation at the end of the video.
4. To overcome problems during the modelling process students not only use heuristic but also *metacognitive strategies*, which can especially be helpful. Different metacognitive strategies such as planning and regulation can be found in the videos.
5. Modelling problems are usually solved in a group. Therefore, heuristic and metacognitive strategies influence the group work process and each member of the group plays a *different role* during the process.

The script created, which considers these aspects, was revised by an expert group, which has already worked with staged videos. Another group of experts in mathematics education afterwards played the role of the students following the script, which was videotaped, and improvised in a second take to adapt the situation to a more reality-based setting. Changes in language as well as in behaviour instructions were made and added to the script. Furthermore, a second revision took place based on expert ratings, where the experts were either specialized in the field of mathematical modelling or in the creation and use of staged video vignettes. Finally, three short videos were made by filming year 9 students, who acted according to the script.

## **Implementing the developed videos**

As described above the university students lacked the ability to implement their theoretical knowledge sufficiently during the modelling days. The project aims at providing an innovative learning environment, which offers the opportunity to practice the implementation of knowledge by using staged videos as well as five extracts of recorded lessons.

Important theoretical constructs are conveyed as described above but also exemplified through the staged video vignettes: The videos are used to practice noticing relevant aspects based on theoretical constructs discussed before in a short time. Furthermore, the following discussion and reflection in plenum can lead to a better understanding of the lesson shown and improve the perception and interpretation of the next video. Moreover, decision-making is required when evaluating the possible interventions at the end of the video. The repeated use of these videos with different content and various modelling-specific problems is sought to lead to a better application of knowledge. This will become clear during the last part of the course, where the future teachers supervise students at school

during a two-day modelling project and can implement their knowledge and skills in their performance.

## Looking ahead

Making knowledge applicable is an important aspect in teacher education. This innovative project, which uses videos during the described modelling seminar to foster future teachers' perception, interpretation and decision-making, is embedded in a study evaluating the development of teachers' situation-specific competencies and its underlying dispositions as well as the consequences with a mixed methods study design.

Hence, video vignettes serve a dual purpose: Staged videos as well as recorded video clips are used during the modelling seminar to enhance situation-specific competencies. Furthermore, staged videos are used in a pre-post-test design to analyse the development of situated competencies. The Pre- and Post-test also includes a questionnaire, which assesses through closed and open questions knowledge facets based on the model by Borromeo Ferri and Blum (2010). Therefore, the effect of knowledge on the situated competencies and the development of both aspects can be examined. During the modelling days a few selected university students are filmed while supervising the students. Thus, their performance can be observed and all aspects of the PID-model can be analysed and possible connections identified.

In the long term, all three staged videos can sustainably be used in the modelling seminar without further effort or may serve as a means for assessment of the university students' development and performance.

*In this paper we investigate the potential in extending Model Activity Diagrams (MADs) as an analytical tool for studying the activities students engage in when working on modelling problems. By including a sub-division of the task students work on in the MAD framework, we are able to make a more nuanced analysis that in a more explicit way reveals the structure of the students' modelling process. The framework is applied to groups of students engaged in solving a Fermi problem using a two-level analysis, and the result is contrasted and discussed by comparing the outcome of the analysis with the corresponding analysis made using the modelling cycle. In addition, possible applications of the extended MAD framework in research and the training of teachers are discussed.*

*Keywords: Mathematical modelling, Fermi problems, modelling activities diagrams.*

## Introduction

In this paper we present a qualitative study focusing on developing a tool to aid researchers in the analysis of mathematical modelling processes students engage in. Existing literature features several theoretical developments that attempt to describe students' modelling processes. Most of these theoretical perspectives are based on the division of the students' work into two domains by separating the real world from the mathematical realm. It is mostly accepted that students go through different stages in a cyclical manner when engaged in modelling as exemplified for example by the so-called modelling cycle of Blum and Leiss (2007). Although this cyclic representation of modelling provides a useful tool and heuristics for teaching and thinking about modelling, there are some concerns and limitations when it comes to its applicability as a research tool.

Firstly, the modelling routes that students are seen to follow when engaged in modelling are complex and typically deviate from the depicted idealized view of the modelling cycle (Borromeo Ferri, 2007). Secondly, some studies (e.g., Ärleback, 2009; Czoher, 2016; Aymerich & Albarracín, 2016) highlight the difficulties in identifying the different stages of the modelling process of students' work in a reliable way. In an attempt to provide a complementary perspective on these issues and to partly overcome these difficulties, we propose a construct that extends Modelling Activity Diagrams (MADs) to characterize the activities of students engaged in a mathematical modelling process as an alternative analytical tool to the modelling cycle. To do this, we sought to extend the information provided by the original MAD framework by including a representation of the internal structure of the sub-problems the students engaged in when solving a problem and applied this extended MAD framework on video-data of students aged 15 to 16 solving a Fermi problem (see Ärleback, 2009).

Thus, the aim of this paper is to explore the possibilities of Modelling Activity Diagrams, extended to also explicitly include and represent the structure of the modelling problem in question as well as the complexity of modelling processes. The goal of this paper is to determine whether this extended tool actually provides additional information on the structures underlying the activities the students engage in compared to analyses based on the modelling cycle or the original MADs.

## **Representations of mathematical modelling: The Modelling Cycle and Modelling Activity Diagrams**

In the general discussion, mathematical modelling is often considered to be cyclical in nature, involving going back and forth between the real world and the world of mathematics. Even though there are several ways of conceiving and viewing the structure of a modelling process, it is generally understood that it can be divided into different stages and that the students go through these sequentially, moving from one stage to the next once they consider the work in the current stage has been concluded satisfactorily (Perrenet & Zwaneveld, 2012). The conceptualization of Blum and Leiss (2007) has been widely used to describe the modelling process but has shown to be difficult to use as a tool for analysis when it comes to describe and explain the students' work (Borromeo Ferri, 2007; Ärlebäck, 2009; Czoher, 2016; Aymerich & Albarracín, 2016).

When faced with the need to describe the modelling processes implemented by students, Borromeo Ferri (2007) proposed so-called individual modelling routes with the aim of broadening the modelling cycle's analytical reach. These routes consist of arrow diagrams that show students' work within the theoretical diagram of the modelling cycle, illustrating the non-conformity of students' work relative to the modelling cycle as well as students' seemingly stochastic modelling behaviour. Acknowledging the work by Borromeo Ferri, Ärlebäck (2009) introduced Modelling Activity Diagrams (MADs) as a bi-dimensional graph that depicts the types of modelling activities the students engage in when solving novel modelling problems. The activities proposed by Ärlebäck (2009) and used to characterize the modelling processes in terms of MADs can be found in Table 1.

R: Reading	Reading the statement of the task and understanding it
M: Modelling	Simplifying and structuring the task mathematically
E: Estimating	Making quantitative estimates
C: Calculating	Performing mathematical calculations, such as arithmetic calculations, working with equations, drawing sketches or diagrams
V: Validating	Interpreting, verifying and validating the results, calculations and the model itself related to the real-life context of the problem
W: Writing	Summarizing the findings and results in a report, drafting the solving process as well as the solution

**Table 1: Activities that make up MADs**

## Mathematical modelling and Fermi problems

The use of so-called Fermi problems in our work allows us to propose simple situations that require students to engage in mathematical analysis that promotes the construction of models. Following Ärlebäck (2009), we consider Fermi problems to be open, non-standard problems that require students to make assumptions about the problem situation and estimates of certain quantities before they engage in, often, a series of simple calculations. Efthimiou and Llewellyn (2007) characterised Fermi problems based on their formulation since these always appear to be open questions offering little or no specific information to the solver directing them in the solving process. The key aspect to Fermi problems from the perspective of mathematical modelling is the need to conduct a detailed analysis of the situation presented in the statement of the problem with the objective of decomposing the original problem into simpler and connected problems – addressed as sub-problems in the present work – to reach a solution to the original problem by means of reasonable estimates and reasoning.

Some research studies conducted to date on the use of Fermi problems in the teaching and learning of mathematics have been shown to facilitate the introduction of mathematical modelling in primary and secondary school classrooms as well as at college level. While engaging in solving Fermi problems primary students develop new mathematical knowledge in arriving at their solutions (Peter-Koop, 2009). Social relations and extra-mathematical knowledge in the problem-solving situation are also relevant to the problem-solving process (Ärlebäck, 2009). Czoher (2016), who used Fermi problems to analyse university engineering students' performance in terms of MADs, confirms that the MADs reveal the students' mathematical thinking about variables and constraints related to the problem contexts. Czoher adds an interesting dimension to the interpretation of the MAD when she writes that when a task has become routine for an individual, the modelling route displayed by that individual for solving that particular task resembles the idealized working process of the modelling cycle (e.g., Blum & Leiss, 2007).

## Methodology

The aim of our research presented in this paper is to develop an extension of Modelling Activity Diagrams and to investigate the potential and possibilities of this extended framework. For this purpose, we explicitly included a representation of the sub-problems elaborated by the students to achieve their objective within the activity (e.g., solving a Fermi problem). The data analysed in the paper was collected in a secondary school located in the metropolitan area of Barcelona and consists of video-recordings of the problem-solving processes of groups consisting of three regular Grade 4 secondary school students (ages 15 to 16) engaged in solving a Fermi problem. The groups were constructed by choosing students that suggested well elaborated and different solution strategies to previous Fermi problem. The problem the students worked on deals with the estimation of the number of objects needed to fill a large volume presented in a specific context. The problem statement provided to the students was the following:

Water is a scarce resource and it is necessary to be aware of the use we make of it. We have organised a debate to address the amount of water used for different purposes, and, in order to provide concrete data, we need to answer the following question: How many bathtubs can we fill with the water of a public swimming pool?

The video-recordings were transcribed in terms of the utterances the students made, with each students' single uninterrupted verbal contribution considered as one utterance. We analysed the data in two levels: first both in terms of the modelling cycle and the MAD framework respectively. In the second level of analysis we re-analysed the data and additionally identified the sub-problems the students engaged in to solve the main problem and incorporated this information graphically in the MAD. Notably, the generally most common model used for this type of problem and this particular age-group of students is the iteration of a unit (Albarracín & Gorgorió, 2014), in which the students determine the volume of a (larger) object and compare it to that of its containing (smaller) base units, decomposing the problem into three sub-problems – the calculation of each volume and a final comparison – as illustrated in the diagram shown in Figure 1.

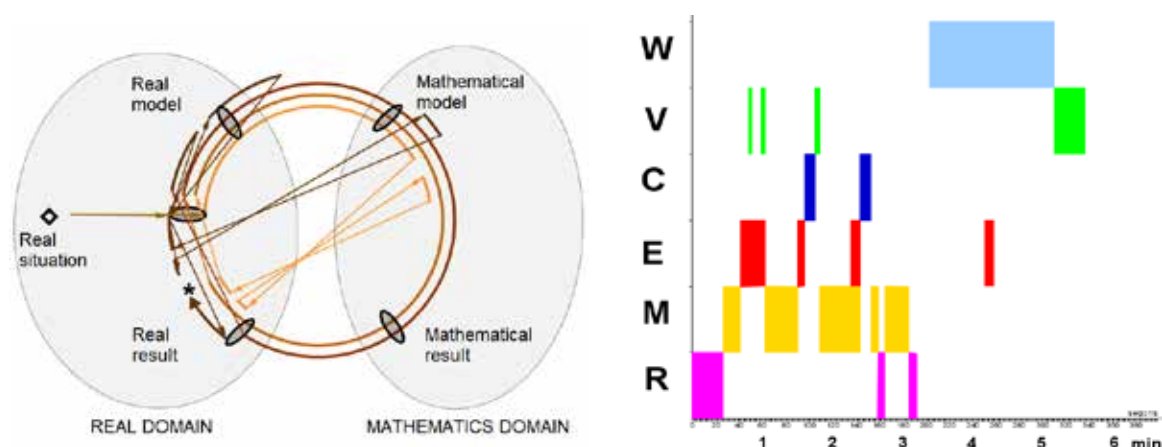

**Figure 1: Structure of the Fermi problem used in this study**

With this second level of analysis based on identifying the modelling activities manifested through each sub-problem, we intend to describe and investigate the relationship between the MAD and the underlying structure of the modelling processes induced by the sub-problems.

## Results

The students in group A worked on the assumption of a swimming pool being 25 metres in length, arriving at an estimated result that 480 bathtubs would fit inside the swimming pool. The participation in the discussion was unevenly distributed, and the problem was mainly modelled and discussed by Ada and Arnau, while Aina drafted the report and participated in the validation process. The total number of utterances for the members of the team were: Ada, 33; Aina, 26; and Arnau, 37. The result of the analysis of group A's performance using the modelling cycle of Blum and Leiss (2007), as was also done in Aymerich and Albarracín (2016) and by focusing on identifying the different stages in the modelling process the students engaged in, can be seen in Figure 2a. This figure shows a complex problem-solving process involving many of the stages in the modelling cycle. One can note however, that none of the students' iterations in terms of modelling routes are closed in the sense of completing (the) stages in the modelling cycle in a clockwise manner, and that the students seem to be struggling in the initial phase of solving the problem. Using the MAD framework Figure 2b illustrates the switching between the different activities the students engaged in, the complexity of how the groups' modelling process unfolded, and hence conveys, analogous to the representation in Figure 2a, a picture of a somewhat disorganised process.

**Figure 2: a. Analysis of group A's modelling route in terms of the modelling cycle (left); b. Analysis of group A's modelling route in terms of the MAD framework (right)**

If we turn to the analysis including the division into the sub-problems that the students engaged in and how the coded activities are distributed in relation to these, a more nuanced and clear structure is revealed. The MADs show the activities the students engaged in along a timeline, and departing from this, the extension of the MAD is generated by introducing a graduation of intensity of colour to differentiate each of the sub-problems in which the students work. In the lower part of the graph, the specific sub-problems are labelled. In this way, the extended MAD provides a representation merging both the identified modelling activities and the sub-problems the students addressed.

**Figure 3: A MAD with the sub-problems group A engaged in during their problem-solving process**

Figure 3 shows the activities the students engaged in to solve each of the sub-problem they tackled. The students started working on deciding the size of their swimming pool of choice and estimating its volume (sub-problem one), and then worked on estimating the volume of a bathtub (sub-problem two). The third sub-problem consisted of calculating the number of bathtubs that would fit in the swimming pool, before finally re-organising the information obtained in order to present a solution and write the report.

Coming back to the point made by Czoher (2016), that students' modelling processes of routine problems tend to better line up with the stages in the modelling cycle, we conclude that this is by no means obvious in terms of students' modelling routes as depicted in Figure 2.a or the activities in the MAD in Figure 2.b. Rather, the impression conveyed by these representations is that the problem solving process the students engaged in is ill-structured and complex. However, the resulting diagram from the extended MAD analysis (Figure 3) provides a more accurate and nuanced representation of the students' engagement within the problem. The MAD in Figure 3 clearly reveals the structure of the activities the student engaged in when solving the problem and shows that the model needed to solve the problem was accessible to them and that they controlled all the details needed to reach a solution. To contrast this straight forward problem-solving process, we illustrate the activities engaged in by a different group of students in solving the same problem. Figure 4 shows that the extended MAD for a second group B and reveals some difficulties in their solution process. These students also calculated the volume of a bathtub and a pool, but they initially used different units in the respective calculations. Hence, which can be seen between 5:39 and 7:41 in Figure 4, they had to decide how to go about to combine their calculated values in order to obtain a result.

**Figure 4: MAD with separation into sub-problems for group B's modelling process**

The comparison between the different approaches to analyse the data leads us to conclude that the extended MAD do facilitate an analytical narrative that is closer to the actual activities the students engage in. It does this in the sense that the extended MAD provides more localised information that allows for a clearer and more detailed interpretation of the students' actions and decisions.

## Discussion and conclusions

From a methodological point of view, we reaffirm the idea that characterizing the different activities students engage in when solving a modelling problem is straighter forward and clearer in terms of MAD activities compared to that in terms of stages of the modelling cycle. However, we must emphasize that analysing the tasks carried out by a group is a complex task since we can only rely on the observable elements the collected data provide. Sometimes the students in a group split their focuses and interests when working towards the solution, resulting in the students not working together. Due to their inherent structure, the MAD diagrams make it possible to show this fact explicitly by mapping out different bars for the different activities for the time period in question. In this way, we consider MAD diagrams to be both a richer and more robust tool from a methodological

point of view when it comes to make and visualize the connection between the activities the students actually engage in during the problem-solving process and the codes aiming to capture these activities explicitly. From the point of view of the development of an analysis tools, Fermi problems appear suitable as a type of modelling activity for validating the utility of extended MAD. To investigate limitations, the framework needs to be applied to more complex situations where students are engaged in other types of activities (statistical data collection, measurement, prototyping, ...) as well as to the different parts of larger and more complex modelling problems and projects.

Another aspect to note is that the results show that even in the case of students engaged in solving a Fermi problem that is accessible to them, the modelling process involved in arriving to a solution is complex. This complexity is manifested in the large number of the instances that students engage in different activities needed to characterize the problem-solving process, but also in the significant differences between the problem-solving processes of the different groups. This study allows us to affirm that although this complexity exists, the extended MAD framework facilitate us to reveal the internal structure of the proposed Fermi problem, and thus more clearly showing the work pattern of the students. Group A's initial MAD (Figure 2.a) shows a complex problem-solving process that is, however, clearly possible to divide into the solving of several sub-problems as displayed using the extended MAD (Figure 3). For this group the problem given did not pose any great difficulties, neither from a decision-making point of view regarding the modelling process, nor in the workings of the mathematical tools used. This results in an extended MAD of the students' problem-solving process that in a trustworthy way reflects the activities the students engaged in. In part, the modelling behaviour displayed by the students in this group is concurrent with the findings of Czoher (2016), that when students experience the modelling problem at hand as routine, the problem-solving process is more or less straightforward.

This latter fact suggests the possibility of using the extended MAD as a way of representing the activities students engage in during modelling in teacher training programmes. In this context, the extended MAD can be used as the point of departure for discussions on students' performance in different stages of the modelling process and to differentiate between those instances where students have difficulties compared to those in which students make progress and are constructing (sub-) solutions easily. In this sense, and in line with the benefits reported from the use of modelling cycles in teacher preparation courses (Sevinc & Lesh, 2018), we understand that extended MADs can act as an access point or as an element to foster other types of discussions, allowing students' procedures to be connected to the content used. An example of this extra explanatory information the extended MAD makes it easier to identify, is the activities the students in the second group engage in when they detected the inconsistencies in their calculated values due to the units chosen when considering the volumes of the pool and bathtub respectively. The lack of specificity in the formulation of the given problem is part of the nature of Fermi problems and promotes discussion between students, as well as connecting mathematical and extra-mathematical knowledge. The analytical approach developed in this study shows that extended MAD diagrams can be a helpful tool to visualize some of these hidden elements, and that previously seemingly messy and haphazard problem-solving processes can be understood as highly structured. In fact, we are hopeful that extended MAD diagrams can be further developed and readily applied to study also mathematical modelling

processes beyond mere Fermi problems. Given that the MADs were designed to specifically study these types of problems, one of the activities included in the original analysis is estimation, but we suggest that this activity is broadened, or complemented with other types of activities, so that activities such as making measurement, statistical data collection, experimentation or simulation are included in the next version of the extended MAD framework.

*This paper aims to explore and discuss the use of simulations with physical models and prototype construction in a mathematical modelling activity in a context of science, technology, engineering and mathematics (STEM). This study aims to understand the role of simulations and prototypes in student activity and how the use of prototypes and simulations modifies the mathematical modelling cycle. The study is based on a teaching experience in two 9th grade classes. From the analysis we can say that the integration of simulations and prototype construction in an educational STEM context is an important factor for students in assigning meaning to the various phases of the mathematical modelling cycle and in working effectively through those phases.*

**Keywords:** *Mathematical modelling cycle, prototype, simulation, STEM.*

## Introduction

In the last decade, both in conference papers and in articles published in various journals on science and mathematics teaching, the emphasis has increased regarding the educational plea for the integration and connection between knowledge, methods and concepts of different disciplines in school. This movement, in particular, embraces the perspective of an interdisciplinary teaching of Science, Technology, Engineering, and Mathematics, known today as STEM Education (acronym for Science, Technology, Engineering, and Mathematics).

The drive towards interdisciplinary teaching has been a constant trend both in reports from the PISA studies (OECD, 2016) and in official curricular guidelines from different countries, endorsing more relevant, less fragmented, and more stimulating learning opportunities for students (Furner & Kumar, 2007). STEM education represents an effort to combine science, technology, engineering and mathematics in a single classroom or lab or in more open and interconnected multipurpose school facilities, based on the relationships that can be generated between contents and real-life problems, in which the four areas of knowledge may be relevant, although they do not have to be present at the same time (Moore, 2008; Zawojewski, 2010; Michelsen, 2006).

Many examples of studies within a STEM perspective involve experimental work using simulations and physical materials where the engineering design process is put into practice in the learning activities and projects (Stohlmann, Moore, & Roehring, 2012). In some cases, the activities combine engineering and mathematics and the mathematical modelling cycle is used as a reference for the organization and orientation of the work to be developed with the students (Mousoulides & English, 2011; Gallegos, 2018). The aims may include learning and exploring new aspects involved in a real system, or designing new products and processes.

In this article, we consider the combination of engineering, biology, and mathematics, in a modelling task where the simulation of the situation and the mathematical modelling of real-world

systems are involved. The three research questions underpinning a larger research study, which is the basis of this partial report, are the following:

- (1) What is the role of simulation in the students' mathematical modelling activity when solving problems taken from a STEM context?
- (2) What is the role of a prototype in a mathematical modelling activity within a STEM context?
- (3) How does the use of prototypes and simulations impact the mathematical modelling cycle phases?

## Theoretical Framework

The theoretical underpinnings of the study are here generically presented, under the intention of making salient a pedagogical perspective on the use of simulations with physical models, aligned with an engineering and mathematical modelling approach for teaching and learning mathematical concepts and ideas that are interconnected with other areas of knowledge, like hand biometry, for example.

### Engineering Modelling Eliciting Activities (EngMEAs)

An engineering model eliciting activity (EngMEA) is formulated from a real-world problem, which is usually framed as a response to a customer's request. Its design and implementation is supported by the broader framework of the Models and Modelling perspective (M&M) (Lesh & Doerr, 2003; Diefes-Dux & Imbrie, 2008). The accomplishment of the task usually requires one or more mathematical concepts as well as engineering models and processes, which are not openly specified in the problem (Mousoulides & English, 2011). The fact that there is a client to whom a response or result should be provided seems to be a relevant element in this type of task, since it contributes to make the context of the problem more credible for the student, and the solution to be found is not abstractly required, but rather has a presumed recipient (Carreira & Baioa, 2017).

In this perspective, when solving the task, students should bring about their knowledge to formulate a mathematical model that can be used or applied by the client for the solution of a given problem or other similar problems (Diefes-Dux & Imbrie, 2008). An EngMEA type of task may, under adequate settings, promote the ability to develop conceptual tools and to construct, describe and explain complex systems; it also brings forth communication and collaborative work. An EngMEA should be elaborated according to the six principles stated below (Table 1).

Principle	Description
Construction of the model	Requires the construction of an explanation, description or procedure leading to a meaningful mathematical model development according the user's needs.
Generalization	The model must be useful to the user, sharable, re-usable and modifiable.
Documentation of the model	Students should document their activity and their thinking explicitly in the form of a report in some communicational setup.
Reality	The context and form of the task must be credible in order to promote a meaningful interpretation by the students, according to their levels of

	mathematical knowledge and general knowledge.
Self-assessment	The task should contain criteria that students can consider for testing and reviewing the model found.
Effective Prototype	In addition to the mathematical model, a physical/metaphorical prototype may be produced as a real outcome and as a response to a customer.

**Table 1: Principles for the development of an engineering model-eliciting activity (adapted from Diefes-Dux & Imbrie, 2008)**

In the present study, a simulation of the situation, by means of physical models, is expected to be carried out as a support for the production of the effective prototype.

### **Relation between simulation and prototype**

Pollak (2003) argues that a major obstacle related to the integration of mathematical modelling in the classroom is the need for students to understand how to connect mathematics with the rest of the world. One difficulty has to do with the lack of a clear formulation of a conceptual model (which implies an understanding of the problem, of the relevant conditions, and forms of mathematization). A way to overcome this obstacle is giving students the opportunity to engage in performing real simulations, since a simulation is an imitation of the real situation, is closely linked to experimenting, predicting, testing, solving problems, imagining alternative solutions, making the situation real, visible and tangible through representations conveyed by physical models.

In production processes, the simulation with physical models allows observing the system, predicting, supporting decisions, modelling, verifying product quality and performance prior to marketing, and refining production processes (Landriscina, 2013); such physical models offer means that produce behaviours, reproduce some aspects of a system, create a variety of reactions that depend on actions and assist on testing hypotheses in a research problem.

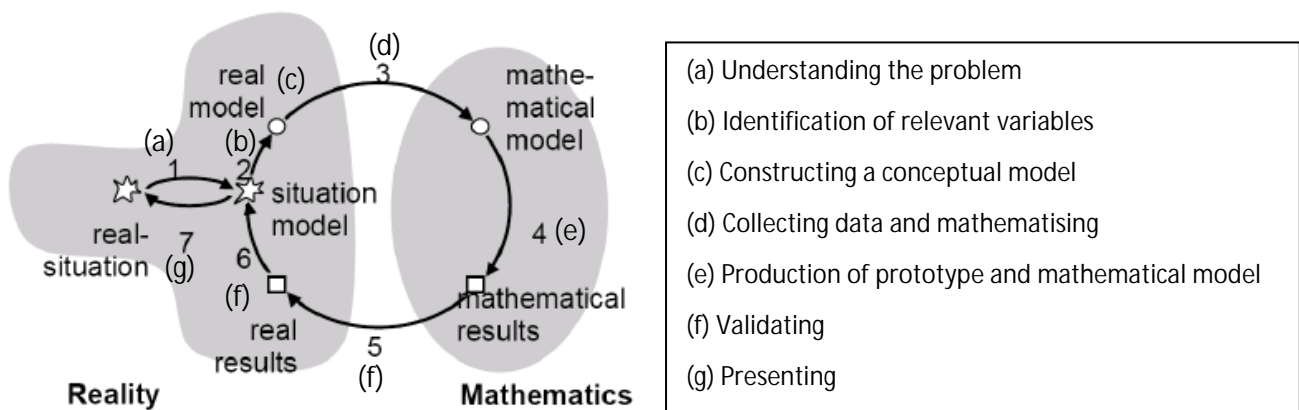

One of the fundamental aspects of a simulation lies on its close relationship with a model, in the sense that it establishes a representation of the real world, whether the model is an image or scheme, an object built to scale, a formula that can be used during a simulation, or even the product of the simulation (Gilbert & Boulter, 2000). The use of a physical model supports the exploration and manipulation of the situation until the creation of a final model (physical or conceptual) that can be called a prototype. The concept of prototype is the basis of the engineering design process where simulations and mathematical modelling are abundantly present, being the prototype a solution to the original problem.

### **Mathematical modelling and engineering design process**

According to Birta and Arbez (2007), the modelling and simulation process in an engineering context, where the objective is the creation of a prototype, consists of six essential steps: (1) The description of problem/project; (2) The construction of a conceptual model of the system; (3) The simulation with physical models; (4) The creation of a prototype and associated mathematical model; (5) The prototype validation in terms of credibility and stability; and (6) Obtaining an end product. These steps are repeated until a satisfactory result is obtained.

Something very similar is typically found in the description of the mathematical modelling cycle (Blum & Leiß, 2007), where the main steps are described as: (1) Understanding the problem; (2) Simplification of the original situation; (3) Mathematizing; (4) Working in the mathematical domain; (5) Interpretation of the result obtained; (6) Validation; and (7) Presentation of results.

The common points between these two forms of conceptualizing the processes that involve reality and the search for a solution to a given problem are evident. Thus, it seems reasonable to admit that both descriptions can be conformed to the other as suggested in the following sequence (Figure 1): (a) Understanding the problem; (b) Identification of the relevant variables in the situation to be modelled; (c) Development of a conceptual model; (d) Data collection through simulation and forms of mathematization; (e) Production of a prototype and associated mathematical model; (f) Validation of model and prototype through stability and credibility; and (g) Presentation of final product and final mathematical model. This is a cyclical process that can be fully or partially repeated, depending on the validation of the prototype or the mathematical model.

**Figure 1: The mathematical modelling cycle coupled with prototype development**

### Methodological approach

In our study we used physical models in tasks that involved problems driven by the scenario of a request from a client. All the tasks involved simulation and practical work. According to studies that share similar elements, design-based research has been adopted (Cobb, 2000; Kelly et al., 2008). Two classes (46 students aged between 13 and 15) participated in this study. Students were organized in the class into 4 or 5 groups and received identical sets of physical materials and instruments for the development of simulations. The empirical data here addressed were collected from the third out of totally five modelling tasks implemented during the school year, through video and audio recording of group work, as well as detail photographs.

Each modelling task was designed according to a structure that involves four parts: (1) Introduction of the task (when the situation and the various elements are presented and clarified); (2) Practical work with physical models, involving data collection; (3) Representation, analysis of collected data and construction of a prototype; and (4) Preparation of a written report and sharing and discussion of the products obtained.

The task refers to the creation of a biometric database and to the development of a recognition system through biometry/hand geometry. The students had at their disposal a set of paper images of their own hands (obtained through photocopies) and the purpose was to create a recognition system

that validated the biometric data of the elements of each group and rejected those of a person who did not belong. After a prototype of such a recognition system was created by each of the groups, a new image of an unidentified hand was given for testing and validation of the respective prototype.

The categories created for the analysis of the data from the implementation of the biometric recognition task refer to the general purpose of perceiving how the simulation and the construction of a prototype play a role in the mathematical modelling activity of the students and, in particular, how they integrate it in the mathematical modelling cycle. Thus, the categories are defined in terms of the phases of this cycle, as described theoretically (Table 2).

Categories	Prototype development	Modelling cycle phases
<b>understanding</b>	Simulation Prototype construction Prototype testing	Ⓜ (a) Understanding the problem and the goal to be achieved
<b>exploration</b>		Ⓜ (b) Identification of the relevant variables in the situation
<b>representation</b>		Ⓜ (c) Development of a conceptual model
<b>experimentation</b>		Ⓜ (d) Collection of data and mathematization of the situation
<b>construction</b>		Ⓜ (e) Development of a prototype and associated mathematical model
<b>validation</b>		Ⓜ (f) Model and prototype validation
<b>communication</b>		Ⓜ (g) End product and mathematical model

**Table 2: Categories of data analysis**

## Summary of the results

The selected data were organized to represent the path of the students' work during the task and according to the categories above (Table 2). This path depicts the main features of the students' ways of thinking throughout the task (Table 3).

<b>Understanding</b>	<ul style="list-style-type: none"> <li>• Watching a video about security systems that use biometric data to recognize individuals.</li> <li>• Reading of the task and clarifying questions.</li> <li>• Understanding the problem and the goal.</li> </ul>
<b>Exploration</b>	<ul style="list-style-type: none"> <li>• Naming the biometric database of the group and defining a code for each group element.</li> <li>• Deciding the measures to collect. (Lengths of the fingers, widths of the phalanges; palm area were different choices suggested).</li> </ul>
<b>Representation and experimentation</b>	<ul style="list-style-type: none"> <li>• Collecting information and data from the image of each hand.</li> <li>• Establishing the main variables to use in the mathematical model.</li> <li>• Recording the numerical data in tables.</li> </ul>
<b>Construction</b>	<ul style="list-style-type: none"> <li>• Defining a rule for the process of comparing and checking a given hand with the database elements (conceptual prototype). An example:</li> </ul>

	Finger 1 (Little finger)		Finger 2 (Ring finger)		Finger 3 (Middle finger)		Finger 4 (Index finger)		Finger 5 (Thumb)	
	width	length	width	length	width	length	width	length	width	length
	$\overline{C_1D_1}$	$\overline{A_1B_1}$	$\overline{C_2D_2}$	$\overline{A_2B_2}$	$\overline{C_3D_3}$	$\overline{A_3B_3}$	$\overline{C_4D_4}$	$\overline{A_4B_4}$	$\overline{C_5D_5}$	$\overline{A_5B_5}$
	<ul style="list-style-type: none"> <li>Assuming an approximate match.</li> <li>Establishing an acceptable “margin of error” of 0,2 cm to be taken in the comparison between some given data and the stored data.</li> </ul> 									
<b>Validation</b>	<ul style="list-style-type: none"> <li>Delivering one unidentified hand image for each group.</li> <li>Obtaining the necessary data from the unidentified hand according to the biometric variables of the identification model.</li> <li>Checking whether the “scanned” or “standardized” hand belonged to the group or not, according to the recognition model.</li> <li>Validating the model and the biometric recognition system developed.</li> </ul>									
<b>Communication</b>	<ul style="list-style-type: none"> <li>Preparing and delivering a report describing the steps taken and presenting the data collected, the mathematical model considered for the recognition, and its validation.</li> </ul>									

Table 3: A synthesis of the students’ main processes and actions on the task

## Discussion and conclusions

Much of the students’ thinking and struggling was around the idea of reliability of the process for comparing experimental data with unknown data (of an unidentified hand). The fact that students were simulating a process of capturing biometric data, using full size photos of hands, and realizing the many details and variations of that part of the human body, led them to reflect at length on how to integrate this knowledge in a recognition system performed by a machine, which aims to accept or reject biometric data. Many of the students were quite cautious about creating a model that did not generate false positives, revealing the understanding that the control to be performed by the model would have to be “strict enough” not to allow “a false hand to be accepted”. This resembles what in reality the biometric security systems are concerned with. In fact, a general result from the activity of the students in creating a biometric recognition conceptual prototype was the strong interconnection between ideas and concepts from mathematics, human body biology, and engineering. The idea of creating a prototype engages students on a real attempt to find the most credible model for a real problem in STEM context. The students’ mathematical model for the biometric recognition system was based on the idea of tolerable margin of error. For example, one of the groups assumed that acceptance of an individual would be confirmed in the case where the deviation found for every variable was less than 0.2 cm. Otherwise the system would reject the individual as unrecognized. They therefore based their model on a logical rule of the type if-then-else. The value of 0.2 cm was chosen through the scaling of the hand. The students decided to spread their hands against the table to get an indication of a tolerable dilation of the hand.

The work with physical models in a simulation, such as the use of the actual images of the palms of the students, was a facilitating element for the need to collect real data and for the development of a conceptual model of the situation. The identification of a set of variables to be used was, from the beginning of the activity, an important source of exploration of the situation in the various groups. Different groups considered different ways of defining the measures they assumed as hand identifiers. Thus, the simulation based on physical models has one clear effect over the emergence of different conceptualizations and ways of approaching the real problem; the task allowed students to create different identification criteria for the biometric database.

The ideas of variability, and error or deviation were the focal points of the mathematical approach to the construction of a recognition prototype. This prototype, in turn, elicited a recognition model, which was founded on mathematical ideas and concepts.

Being in the position of obtaining a prototype, that is, of imagining a data capture system and a model aimed to accept or reject new data by comparison, helped students to understand that their model would have to be reliable, that is, it would have to be tested with a new simulation. This gave added meaning to the process of acquiring new data from an unidentified hand, consistent with the system of variables previously defined for data capture.

The mathematical modelling cycle phases are not modified by using simulation and prototype. The students go through all the phases realizing micro modelling cycles.

In general, we conclude that the use of physical models and simulations in experimental tasks, involving the construction of a prototype, promotes the activity of mathematical modelling under conditions that reveal an evident parallelism with real settings where solutions for real problems are searched. Students are faced with genuine obstacles that do not always arise in other types of problems and use their own everyday knowledge and concepts to find ways of establishing the relationship between mathematics and reality. Thus, the integration of simulations and prototype construction, in a STEM educational context, is an important factor to make sense of and also to perform the various steps of the mathematical modelling cycle, so that they become part of a coherent entire process and not just conventional steps to accomplish.

*This article presents a teacher education activity with pre-service Primary school teachers who are asked to address modelling problems before describing their activity using new discursive and conceptual tools. The terminology of modelling and the questions-answers maps are proposed to enrich the logos of teachers' modelling praxeologies, that is, to provide future teachers with a discourse—a logos—to explain and analyse the modelling praxis.*

*Keywords: Modelling, teacher education, mathematical discourse, anthropological theory of the didactic, praxeologies.*

### Introduction: Teacher difficulties with the modelling discourse

When teaching mathematics is considered as the teaching of already-produced knowledge (concepts, procedures, properties, etc.), teachers dispose of discursive resources to talk about the content at stake: “Here we can use proportionality”, “Be careful with the distributive law”, “The problem leads to a quadratic equation”, etc. All these resources have been elaborated during long processes of didactic transposition (Chevallard, 1985) and can be found in textbooks, syllabi, curriculum guidelines, etc. They belong to what is called the *knowledge to be taught* and appear as crucial tools for teachers and students to manage learning processes, to talk about what is already done, what is still to be done, what mathematical tools can be used, what difficulties might appear, what mistakes have been identified, and so on.

In contrast, in the case of teaching modelling, the content at stake is not only a set of mathematical contents that are to be known and used to solve problems. Modelling is also taught as a process to follow, where all the steps—and not only the final result—are equally important. In this case, teachers and students are not always provided with the appropriate words or discursive elements needed to describe the different steps of the process.

The importance of language in teaching and learning modelling has been pointed out by many researchers (Barbosa, 2006; Borromeo Ferri & Blum, 2010; De Oliveira & Barbosa, 2013; Doerr, 2007). For instance, focusing on the students' performances, Redmond, Brown and Sheehy (2013) propose to use “the principles of collective argumentation to enable students to analyse mathematical contexts, to synthesise strategies to mathematize these tasks, and to communicate solutions and conclusions to others.” (p. 13). This paper addresses the problem of the teachers' lack of discursive tools to teach modelling processes and how it can be addressed through teacher education processes.

### Research problem: mute modelling praxeologies

In this section, we analyse the lack of words in teaching modelling using the anthropological theory of the didactic (ATD). In spite of a diversity of representations (Perrenet & Zwaneveld, 2012), there

is a widespread consensus about the modelling process, and its decomposition in different steps synthesised in the diverse versions of modelling cycles, where models are built and used to produce knowledge about a given piece of reality considered as a *system*. As Serrano, Bosch, and Gascón (2010, p. 2193) explain: “the productivity of the model, that is, the fact that it produces new knowledge about the system, requires a certain ‘fit’ or ‘adaptation’ to the system. This process is rarely done once and for all. It requires a forth and back movement between the model and the system, in a sort of questions-answers or trial-error dynamics.”

In the ATD, mathematical activities are described in terms of praxeologies. A praxeology is the connection between know-how (*praxis*), made of types of problems and techniques to solve them, and a discourse about the praxis (*logos*), composed of descriptions, justifications and theoretical organisations of the problems and techniques. Any human activity (solving an equation, driving a car, combing one’s hair, etc.) can be assigned to a praxeology or a set of praxeologies, with a more or less developed praxis and logos. We use praxeologies to describe both the activity of modelling and the teaching of modelling. In a teaching situation, the mathematical knowledge at stake is commonly revealed through the teacher’s discourse, which updates, describes, explains, justifies, questions and validates the knowledge aimed for. Wozniak (2012b, pp. 65–66) considers three kinds of mathematical praxeologies in teaching situations: “mute”, “weak” and “strong” praxeologies. A “mute” praxeology is one with its *praxis* component visible only, that is, the types of tasks and techniques used to carry them out without any explicit discourse to describe them. In a “weak” praxeology, the *logos* component is visible through the parts of the technique used, but the discourse is limited to the description of the technique through an incomplete formulation. Finally, a “strong” praxeology links its two components, the *praxis* and the *logos*, dialectically.

In the case of modelling praxeologies, Wozniak (2012a, 2012b) speaks of *mute* praxeologies when the hypotheses about the initial system are not explicitly stated (delimitation of the system), the model used is prebuilt and the work within the model gives results that are not validated against the system. *Weak* modelling praxeologies appear when the hypotheses are formulated but their validity domain is not clearly discussed. In this case, the model is not necessarily prebuilt but will not be validated. To develop them into *strong* praxeologies, all steps of the modelling process should be present throughout a discourse that explains their roles and validates the whole process. Wozniak (2012a) uses the three kinds of praxeologies to analyse five primary school teachers working with a modelling problem. Students are presented the photograph of the boot of a giant’s sculpture with some people around (Figure 1) and are asked to find the approximate giant’s height. The main phenomena observed—and which can be found in other investigations about teaching modelling activities—can be summarised as follows:

- The modelling activity is not identified as knowledge at stake and the modelling process is never questioned or taken as an object of study.
- The delimitation of the system remains implicit and is not discussed; the hypotheses are not explicitly formulated and only the missing data are identified.
- The discussion focuses on the choice of the values of the system variables to apply a pre-established model (proportionality).

- All 5 teachers lead the study towards their own solution, and then reduce the study to the same kind of techniques.
- In all but one case, a single model is used without discussing its legitimacy and validity. Teachers do not use the properties of the system (realism) to evaluate the answers obtained and even directly propose the model to be used.
- The fifth teacher includes discussions about the legitimacy of the measures estimated but does not talk about the domain of validity of the model used.

**Figure 1: Picture of the Giant activity**

Wozniak (2012a) concludes that the modelling praxeologies used in all these classrooms correspond to *mute* or *weak* praxeologies, which emphasizes the teachers' need of new knowledge and tools to deal with this kind of activities. In the following section, we propose an example of teacher education activity that aimed at transforming the *mute* praxeologies into *voiced* ones, that is, modelling praxeologies with a *logos* that give them voice to "talk about" the modelling praxis.

### **How to turn mute praxeologies into voiced ones: the cake box**

The teacher education activity was designed and implemented by this paper's first author. It took place during eight 2-hour sessions with a group of 40 pre-service teachers in their 3<sup>rd</sup> year of a double university degree in preschool and primary school education. Although this activity has been tested since the academic year 2012-2013, we here focus on its last implementation in 2017-2018. Its design follows the first three modules of the proposal of *study and research paths for teacher education* (SRP-TE) (Barquero, Bosch, & Romo, 2018, pp. 3–4).

In the first module, pre-service teachers were proposed a general teaching question: "*How can modelling be introduced in Primary school education? Through what kind of modelling activities? With what kind of shared discourse about modelling?*" In this particular implementation, we used the giant height activity as an introduction, to make the students familiar with a modelling activity. The activity was also used to establish some common terms to refer to modelling: system, model, hypotheses, variables of the system, mathematical results, interpretation, model validation, etc. Some of the main results described in Wozniak (2012a) were also explained to the students. Then, in the second module, we started with the implementation of another modelling activity: the *cake box* (an adaptation of the activity described in Chappaz and Michon (2003)). The following three sessions were devoted to implement the cake box activity with the pre-service teachers assuming the role of *students*. The main goal was to make teachers carry out an unfamiliar mathematical activity that could, to a certain extent, exist in an ordinary classroom. The third module covered three sessions, in which students were asked to analyse the modelling process as it was experienced.

## The cake box and the different modelling phases

The modelling activity starts by presenting the case of a baker who needs help for packing her cakes in boxes. She wants to use the same type of boxes she has been using (Figure 2). The following question opens the activity: “How can we build boxes to help the baker packing the variety of cakes she offers? Which relation does exist between the sizes of the initial material (paper or cardboard) and the dimensions of the resulting box?” From this initial question, the activity is structured in three phases depending on what is given as known (the sizes of the paper, box or cake) and what remains unknown.

**Figure 2: Instructions to build the box and examples of the resulting boxes**

**First phase:** We considered that the paper sizes (width and length) are given and focused on question  $Q_1$ : Which are the dimensions of a box resulting from a paper whose sizes are fixed? Students started by considering some particular cases, such as:

$Q_{1.1}$ : What dimensions of the box resulting from an A4 paper? Is there only one possible result?

$Q_{1.2}$ : If we take an A5 (half A4), do we obtain a box measuring half of the previous one?

$Q_{1.3}$ : Which box sizes do we get from a squared sheet? Do we get a squared-based box?

At this phase, all the students worked using *manipulative* and *measuring techniques*, by concretely building the box and measuring the sizes of the box using different instruments (paper grid, ruler, etc.). This experimental work facilitates to *delimitate a rich system*, which had many possibilities to be extended by considering other paper dimensions and raising new questions about the sizes of the resulting boxes. Students also agreed on which variables had to be considered, for the paper (width and length) and for the box (width, length and height), and how to *agree on a common notation*. Some of the more advanced questions came from the arithmetical comparison of the papers and resulting boxes' sizes: students started formulating the first hypotheses about the likely relationships between the different variables. Most of them referred to relationships of proportionality between the sizes of the paper and the box. Although, in most of the occasions, none of the groups working with these initial *arithmetic-geometric models* could validate their first hypotheses, the possibility to experimentally build new boxes helped them to refuse or refine the hypotheses, but not to validate them.

At the end of this first phase, some of the questions students raised were about a possible relationship of proportionality between the paper and the box sizes, and about how to get a particular sized box. When these types of questions appeared, the modelling activity moved to a second phase.

**Second phase:** It was assumed the baker gave the box sizes she needed and the question  $Q_2$  was stated: Which are the initial paper sizes needed to build a box with some specific dimensions?

Students propose to consider new auxiliary questions with particular sizes of boxes, special forms (squared-based boxes) and possible changes in specific dimensions of the box:

$Q_{2.1}$ : What initial paper sizes do we need to get a box with base of 6cm x 13cm?

$Q_{2.2}$ : How to get a box with a base of 8cm x 10cm and 3cm high?

$Q_{2.3}$ : How to get boxes with a square base (such as: 5cm x 5cm, 8cm x 8cm, etc.)?

$Q_{2.4}$ : How to modify the sheet of paper to get a box with the same base and different height?

Students started trying to use the same *manipulative-measuring* techniques developed in the first phase, by selecting box sizes close to the ones they looked for. Most of them proposed to apply *models of proportionality* to deduce the sizes of the paper, in many occasions expressed by a rule of three (Figure 3, left-hand side). When they estimated the sizes of the paper, they built the box to check if their deductions were true. When students checked that the “rule of three” did not work (as not all variables have relationships of proportionality), they looked for new models. The most common models that appeared were *pre-algebraic* ones obtained by opening the box, analysing the 2-dimensional geometrical pattern and describing the relationships (Figure 3, right-hand side). Some other groups proposed *algebraic models*, by assigning algebraic values to the different dimensions of the paper-box and looking for the algebraic equations synthesizing these relationships.

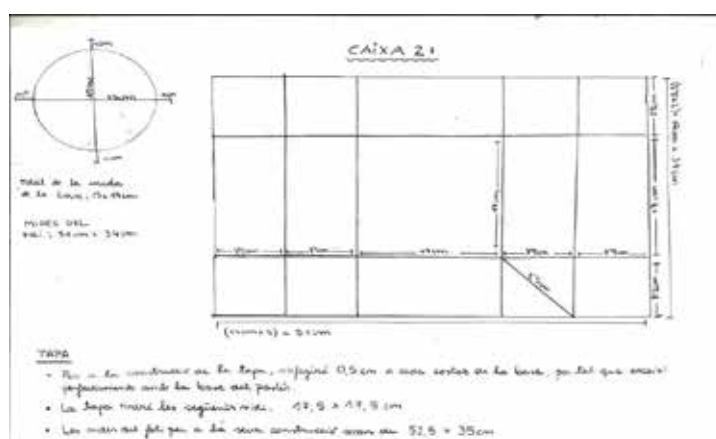

**Figure 3: Models of proportionality (left-hand), pre-algebraic-geometric models (right-hand)**

Concerning the modelling process, two traits may be stressed. First, the modelling work developed in Phase 1 constitutes a productive system from which Phase 2 starts. That is, thanks to the experimental work developed, students have many paper-box sizes collected, which constitutes a rich experimental *milieu* from where some first hypotheses about the relationships were explicitly formulated and against which students could evaluate their answers. Second, in this phase, more advanced models were built by students given the failure of the proportionality model. Several questions about how to reformulate the hypotheses (*Do any of the box or paper variables maintain a relationship of proportionality?*), about the comparison of models (*Are the pre-algebraic and algebraic models expressing the same?*) and about the scope and limitations of the models (*Can we follow working with the pre-algebraic models for all the box cases?*) could be explicitly stated.

This second phase finished when students were able to predict the sizes of the paper/box, without manipulating the paper/box. The following questions were posed by the teacher:

$Q_{\text{final.1}}$ : How can we predict the size(s) of the box (without building it) from the dimensions of the initial paper?  $Q_{\text{final.2}}$ : How to predict the size of an initial paper sheet given the dimensions of the box (without building it)?

**Third phase:** The aim of this phase was to prepare a letter-report as an answer to the baker's demand. A list of the cakes the baker wanted to pack, and their sizes, was provided. Students were asked to prepare the final report for the baker by letting her know about the paper sizes she had to order to pack all her cakes. Moreover, students were asked to add a tray for each box, following the same pattern of construction. At this stage, students had no necessity to build new models, but the main issue was to agree about the way to build the tray (*How many cm do we have to leave between the box and the tray (margins)? Where to add these differences?*). At this stage, they could better formulate the paper-box relationships, and took advantage of using the model (see Figure 4). Furthermore, some time could be devoted to work on how to report the results, given the extent of numerical work and results, with many variables, they had to communicate and organize.

*Translation of the students' proposal:*

**BOX 2:**

Base of the box: 17 cm x 17 cm

Size of the paper: 51 cm x 34 cm

**TRAY:**

§ To build the tray, we add 0.5cm to each side of the box base to guarantee that it fits correctly.

§ The tray base will be 17,5 cm x 17,5 cm

**Figure 4: Pre-algebraic-geometric models for the box and the tray**

### **A progressive construction of the modelling discourse**

When experiencing the cake box activity, participants managed to assume the role of students and carried out the proposed modelling activity although, as they stated, they were not used to this kind of long and open activities. After each session, the working teams (3-4 persons) had to deliver a written report about the modelling activity developed. Participating in the classroom debate and writing the reports was not an easy task for them, as they were conscious they needed new terms to describe the process. At this stage, the previous work with the giant activity was very helpful, since modelling terminology was then introduced. Still, students had many difficulties with, for instance, formulating questions, describing and categorising the kind of models they were suggesting, accepting different possibilities of models and answers, reformulating hypotheses and models, etc.

The instructor decided to follow three main strategies during Module 2. First, she fixed the structure of the reports in terms of: questions studied, data and variables selected, mathematical models considered, answers obtained, new questions opened. This helped participants explicitly describe all these elements. Second, during the debates, she asked participants to explain their proposals and to *create names* to designate the models they were using (arithmetic, geometric, pre-algebraic, algebraic, etc.). This illustrated that there was not only one-way to work on this activity and that several valid models could cohabit. Third, in the debates and reports, the instructor paid special attention to the questions the working teams were posing to help them in their formulations and in relating them to each other.

In Module 3, students were asked to provide an analysis of the modelling work previously carried out, using the session reports and class debates. The instructor proposed to do this work using questions-answers maps (Barquero et al., 2018). She proposed an initial map with the first questions and answers (Q-A) that appeared in the classroom and asked the students to complete it with the description of their own work. This way of describing the modelling process not only provided students with new terminology. It also appeared as an alternative way to talk about doing mathematics, breaking with the usual and “static” way of describing school activities, more focused on concepts, notions and techniques to the detriment of questions, models and provisional answers. Students could also use the Q-A maps to distinguish between their own modelling trajectories—the path followed—and the more complete one they could describe after the work done in class (see Figure 5), thus evidencing the possibility of finding several possible solutions to the same problem.

**Figure 5: Example of questions-answer map used to analyse a modelling trajectory of a group**

## Conclusion

We have seen how Wozniak (2012b) describes the problem of the teachers' lack of discursive tools to talk about modelling processes in terms of *mute* praxeologies, that is, praxeologies where the *logos* component remains implicit. This *logos* is part of the mathematical praxeologies to be taught related to modelling activities. However, it also seems to be a crucial didactic tool to teach modelling—therefore, part of the teacher's didactic praxeology. It is difficult for teachers to highlight some important modelling procedures when they are not familiar with any specific mathematical terminology to talk about models, systems to be modelled, possible fits (and misfits) between models and systems, etc. To start addressing this problem, we propose to use *study and research paths for teacher education* to elaborate new epistemological tools, such as the questions-answers maps, with the teachers as part of the modelling praxeologies to later on develop them as didactic tools to better describe and analyse the modelling activities carried out in classrooms. This strategy needs to be developed, but at the present, it seems helpful to fill in the gap between the traditional way of describing—and conceiving—school mathematics and the new epistemological and didactic necessities raised by the teaching of modelling processes.

# Analysis of textbook modelling tasks, in light of a modelling cycle

Ingeborg Katrin Lid Berget

Volda University College, Norway; [bergeti@hivolda.no](mailto:bergeti@hivolda.no)

*Keywords: Mathematical modelling, modelling competence, task analysis.*

## Introduction

Even if the focus on mathematical modelling in education has increased the last decades, the presence of modelling activities in day-to-day teaching is still limited (Frejd, 2012). This study concern classroom practices comprising mathematical modelling. It is a part of a project, which involves more studies of classroom modelling activities. In this study, we analyze modelling tasks in Norwegian mathematics textbooks evaluating their potential to develop students modelling competency. The tasks are analyzed using the modelling cycle from Blum and Leiß (2007).

## Theory

Modelling competency is defined as “being able to autonomously and insightfully carry through all aspects of a mathematical modelling process” (Blomhøj & Højgaard Jensen, 2003, p. 126). In line with other definitions of modelling competency, the process is essential. The modelling process is often visualized by a cycle. The cycle by Blum and Leiß (2007) sees modelling from a cognitive perspective. This is relevant for this study, which focuses on students’ possibility to evolve modelling competency by solving textbook tasks. The seven steps in the modelling process described in this modelling cycle is 1) Construct, 2) Simplify, 3) Mathematise, 4) Working mathematically, 5) Interpret, 6) Validate and 7) Expose. The steps are operationalized as shown in Figure 1. The study is guided by the research question: Which steps of the modeling cycle are requested for solving textbook modelling tasks?

## Method

Because of the link between the modelling competency and the modelling cycle, it is relevant to make each of the steps a category for the analysis. To identify the categories, identifying questions were made to each modelling step. An example is given, and the identifying questions are presented in Figure 1. The questions are answered in the analysis of the task in Figure 1. This shows that this task only requires step 4, 5 and 6 to be solved.

<p>The table shows the world's population in billions in the period 1970-2010. Here, <math>x</math> is the number of years after 1970.</p> <table border="1"> <tr> <th>Year</th><th>1970</th><th>1980</th><th>1990</th><th>2000</th><th>2010</th></tr> <tr> <th><math>x</math> (years)</th><td>0</td><td>10</td><td>20</td><td>30</td><td>40</td></tr> <tr> <th>Population (billion)</th><td>3,7</td><td>4,4</td><td>5,3</td><td>6,1</td><td>6,8</td></tr> </table> <p>a) Use the population in 1970 and in 2010 to make a linear model for the world's population <math>f(x)</math> in billion, <math>x</math> years after 1970.</p> <p>b) How does the other numbers in the table fit with the model?</p> <p>c) A prognosis from UN shows that the population will be 9.4 billion in 2050. How does this the model in a) fit</p>						Year	1970	1980	1990	2000	2010	$x$ (years)	0	10	20	30	40	Population (billion)	3,7	4,4	5,3	6,1	6,8
Year	1970	1980	1990	2000	2010																		
$x$ (years)	0	10	20	30	40																		
Population (billion)	3,7	4,4	5,3	6,1	6,8																		
<ol style="list-style-type: none"> <li>1. Is the task formulated as an open question, without sufficient numbers given? NO</li> <li>2. Do the students need to make assumptions? NO</li> <li>3. Is the task formulated without mentioning how to solve it, and without mathematical language? NO</li> <li>4. Do the student have to calculate/graph/do a regression analysis? YES, step 4</li> <li>5. Is the task formulated in a context? YES, step 5</li> <li>6. If a model is made, is there a question about how valid the answers from the model is? YES, step 6</li> <li>7. Do the students need to present assumptions done, to explain the answer? NO</li> </ol>																							

**Figure 1: A typical textbook modelling task, and questions to identify the seven steps**

Most of the textbook tasks have several sub-questions, as the task in Figure 1. For more open tasks ‘validate’ was operationalized by the identifying question “Does the task have a given correct answer?” If a correct answer is given, there is no need for validation. The textbooks are from the subject Mathematics 2P (practical mathematics) in second year of upper secondary school (age 17-18). The curriculum recognizes modelling providing an overarching perspective to mathematics, and modelling is one of four main subject areas. The analyzed sample consists of all tasks in the modelling chapters, a total of 514 tasks from the three most used textbooks in this subject.

## Results

#ex		Step in the modelling cycle						
		1) Constructing	2) Simplifying	3) Mathematizing	4) Working mathematically	5) Interpreting	6) Validating	7) Exposing
257	Textbook 1	-	-	-	256	138	29	-
108	Textbook 2	2	2	7	102	70	40	2
149	Textbook 3	1	1	10	131	84	43	1
514	Overall	3	3	17	489	292	112	3

**Table 1: Results**

The result shows that step 1, 2 and 3 are only requested in 3 of the 514 tasks. If the textbook authors have already constructed and simplified the problem, there are no need for the student to expose the answer by explaining which simplifications are done. The first two and the last step are connected.

## Discussion and concluding remarks

The results show that the understanding of mathematical modelling within the textbook tasks are different from the theory used in this analysis. The tasks are from the chapters of the books named modelling. Even if the curriculum states that the starting point in a modelling process is something that actually exists, only 17 of the 514 tasks request mathematizing. Even if 292 of the tasks are formulated in a context, most of them are already mathematized. The tasks are formulated using mathematical language, and numbers are given, as in the task in Figure 1. More studies are needed to say if this understanding of mathematical modelling also is current in the classrooms.

Even if mathematical modelling is one of the four main subject areas in the subject Mathematics 2P, this study shows that working with the textbook tasks of the subject do not provide modelling competency. The starting point for the tasks is often step 4) working mathematically, and not 1) construct the problem from “something that actually exists”, as formulated in the curriculum.

# Assessing Teaching Competencies for Mathematical Modelling

Rita Borromeo Ferri

University of Kassel, Institute of Mathematics, Germany; borromeo@mathematik.uni-kassel.de

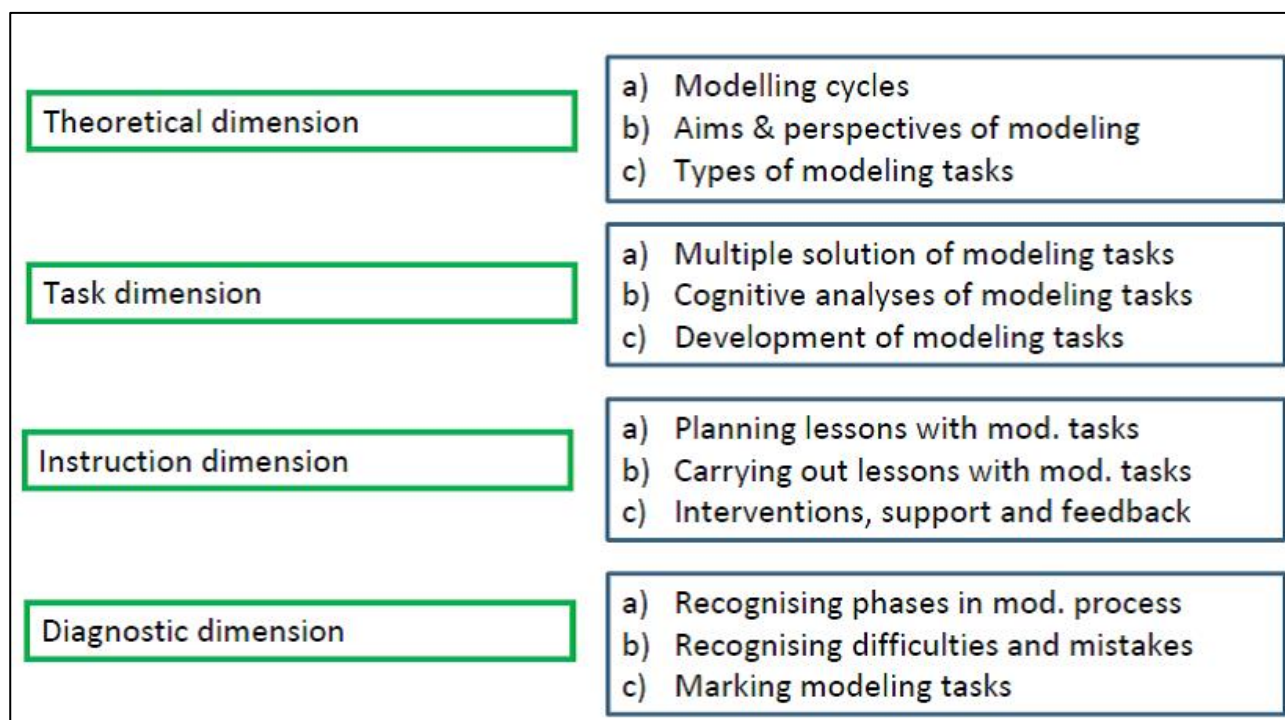

*The question of how mathematical modelling competencies can be assessed has been well investigated and discussed in the last decades within the modelling research field. The test instrument, originally from Haines and Crouch, was adapted for learners in secondary and high-school and as well for teachers in many empirical studies. The results of these investigations also helped to conceptualize the term of modelling competencies. Far more at the beginning of research efforts is the question of how teaching competencies for mathematical modelling, based on the model of Borromeo Ferri, can be assessed. The complexity of the four dimensions is challenging in order to develop a test instrument with the goal to see an increase of teaching competencies after a course on ‘learning and teaching of mathematical modelling’. The paper describes recently developed test items used in an intervention study with prospective teachers, and presents first results of this pilot study.*

*Keywords: Mathematical modelling, teaching competencies, assessment.*

## Teaching competencies for mathematical modelling

Since the beginning of research in the field of mathematical modelling education it is of great interest to get insight into how teachers in school, but also lecturers at university, should teach mathematical modelling to their learners in the best way. Many best-practice university courses or seminars can be found in the literature concerning this aspect (e.g., Lesh & Doerr, 2003; Schwarz & Kaiser, 2004; Borromeo Ferri & Blum, 2010; Maaß & Gurlitt, 2011; Burkhardt, 2018; Vorhölter, 2018). The cited authors describe in their courses or training workshops for mathematical modelling in teacher education several activities and thus competencies, which teachers should learn for teaching modelling successfully. The variety of didactical approaches, contents and aims in these course descriptions are very broad. Thus the conceptualization and operationalization of teaching competencies in mathematical modelling was necessary from the author’s perspective in order to get also a theoretical framework.

Based on a Designed-Based Research (DBL) approach, Borromeo Ferri (2018b) developed, within the last 10 years, a module for a modelling course for university and also for teacher training, which led to a model for competencies needed in teaching mathematical modelling (Borromeo Ferri 2014, 2018, Borromeo Ferri & Blum 2010). The goal is that the lecturer of a university seminar for prospective math teachers or a teacher trainer covers all competencies of the model in a balanced way and sometimes with different emphasis due to the timeline of the course or the workshop. This works very well, because I practiced and investigated these courses since a long time. Figure 1 shows the model with its 4 dimensions and sub-competencies:

**Figure 1: Model for competencies needed in teaching mathematical modelling (Borromeo Ferri, 2018)**

The structure of my modelling courses is based on this model, which means going through each dimension starting with the theory and ending with discussing about assessment in modelling. Step after step the participants gain more competencies and understand how everything is linked together. Due to the aspect that participants should develop a modelling problem, teach it at school and finally reflect on it, a Theory-Practice Balance is given. This greatly helps to understand what modelling means in the school context and in particular that teaching modelling is possible. For more details concerning the full module, the used of modelling problems, materials or teaching methods, see Borromeo Ferri (2018a). The continuous modification of the modelling course is one aspect, a further aspect is of course to measure systematically how teaching competencies of the participants increase during and after the modelling course, which means at the end of a semester or after a teacher training of two full days. Based on the observations and evaluation sheets of the university students and teachers, I can definitely argue that an increase of teaching competencies takes place after these courses, but the goal is to assess this from a scientific and empiric point of view. This is a challenge when recognizing the complexity of the model. Klock et al. (in press) and Klock et al. (2018) also developed a test instrument for facets of a modified version of the model of Borromeo Ferri. This test instrument is piloted and used already in intervention studies.

However, I developed items for the four dimensions of mathematical modelling teaching competencies based on my model in order to get a test instrument. These items were recently applied and piloted with a pre- and post-test design for a university modelling course for prospective secondary teachers, in order to get knowledge on how their teaching competencies increase. In the following, the item development is briefly described, which shall show the difficulties of building scales, but also some examples of final items are presented. Furthermore first results of the pilot study are shown and discussed.

## Development of test items for the teaching competencies

When looking at the model for teaching competencies it becomes clear that items are needed, which should test both declarative and conceptual knowledge. The four dimensions build on each other and are connected. The diagnosis of mistakes in students' modelling process for example is much easier, if the teachers have knowledge about the modelling phases and about modelling tasks. Learning to diagnose does not only mean to give a definition of several types of diagnosis (product oriented/process oriented), but also to practice it with school students and also with concrete examples presented in video clips. The same applies for the topic teacher interventions while modelling. Although this is a strong part within the modelling course, it is not easy to test these competencies.

Within the first approach of test development and evaluation, most of the items were open. This test version was used for 24 prospective secondary and high-school teachers in their fourth semester at university. A prominent open question for the theoretical dimension is: "What is mathematical modelling?", because on the one hand one would expect some kind of definition and on the other hand it is interesting to see what prospective teachers really have understood, when they describe it before and at the end of the course. According to this, very broad answers were given at the end of the course. Often, modelling was described as a process referring to the modelling cycle, for example: "Mathematical modelling means to follow the steps of a modelling cycle." This is not wrong, but also not completely right, because the nature of mathematical modelling is not emphasized. In a further open item the students should draw a modelling cycle, write down and describe the several steps. This is a nice activity, but difficult for coding the results at the end. How to code only partly answers or not precise descriptions? In sum, this kind of test items by using open questions for the teaching dimensions offered a lot of insight of university students' increase of their teacher competencies only on the basis of their elaborate answers and statements from the pre-test to the post-test, but not in the sense of a classical test. Furthermore, the test time was about 45 to 60 minutes, because answers needed intensive writing and the test construction with its complex items does not allow to cover all sub-competencies within the dimensions. Thus the decision for a multiple choice format with closed items was made for assessing declarative and conceptual knowledge in a balanced and economic way for all teaching dimensions.

Like for the previous version, the construction of new test items was based on the content of the modelling course. All items of the new test instrument were developed in such a way that one has to choose a correct answer according to a statement or after the analysis of a written dialogue from learners while modelling. Options between two or five possibilities, depending on the item, are given to pick out the right answer or one has to write down the correct term for which is asked. Thus, this answering format offers the possibility for dichotomous coding. The table gives an overview about the number of items per scale (teaching dimension):

	<b>Theoretical D.</b>	<b>Task D.</b>	<b>Instruction D.</b>	<b>Diagnostic D.</b>
<b>Number of items</b>	26	11	14	14

**Table 1: Number of items per scales (4 teaching dimensions)**

Within the theoretical dimensions the testing of declarative knowledge with 26 items was in the foreground. In the following three examples items are shown.

Here, your theoretical knowledge is asked. Choose, if the statement is right (yes) or wrong (no):

	yes	no
The basis of mathematical modelling are problems from real life	<input type="checkbox"/>	<input type="checkbox"/>
The "Complexity" describes one criterion of a modelling problem	<input type="checkbox"/>	<input type="checkbox"/>

**Figure 2: Example items of the scale "Theoretical dimension"**

For the scale "Task dimension" 11 items were developed, which tested declarative and conceptual knowledge. In order to assess the conceptual knowledge, a modelling problem was given with corresponding solutions of learners. It was asked to choose the right phase of the modelling process, where the solution belongs to. Because of the fact that only one answer from five options is right, one has to analyze the solution more in detail. Not only the knowledge about the terms and the phases is of importance, but to apply it based on own experiences during the course while solving and reflecting modelling problems. The "Instruction dimension" is, compared to the other dimensions, quite hard to assess. First of all it is not possible to test if an individual is really able to teach modelling in the class, nor if the lesson is good or bad. However items were developed, which asked for basics of quality teaching concerning modelling and furthermore about the aspects of teacher interventions as well. Hence 14 items are in the scale "Instruction dimension", which cover declarative and conceptual knowledge. Two items of this scale are shown in Figure 3.

Here, your knowledge about teaching modelling is asked. Choose, if the statement is right (yes) or wrong (no):

	yes	no
The introduction of modelling activities works with over-determined problems	<input type="checkbox"/>	<input type="checkbox"/>
Responsive interventions lead back to the teacher	<input type="checkbox"/>	<input type="checkbox"/>

**Figure 3: Example items of the scale "Instruction dimension"**

In particular the teacher interventions were tested along different short written conversations of learners while working on a modelling problem in the classroom. The levels or activators of the interventions, for example, had to be determined correctly.

The last dimension and scale is the "Diagnostic dimension" with 14 developed items. Like in the task and instruction dimension, both declarative and conceptual knowledge was tested with several items. To diagnose in which modelling phase learners worked and also problems, mistakes and misconceptions were in the focus for the item development. Again, items were used, which showed a conversation of learners working on a modelling problem. Then one right answer has to be chosen.

Diagnose the modelling phase, in which the learners work primarily. Choose one option!

understanding the problem	<input type="checkbox"/>
simplifying/using extra-mathematical knowledge	<input type="checkbox"/>
mathematizing	<input type="checkbox"/>
working mathematically	<input type="checkbox"/>
interpreting	<input type="checkbox"/>
validating	<input type="checkbox"/>

**Figure 4: Example item of the scale “Diagnose dimension”**

A crucial part of the modelling course is the development of students’ own modelling problems, which are finally taught in school. This includes besides planning, executing and reflecting on the lesson also to diagnose learners while they work on the problem. This kind of real life observation is connected with the usage of video-clips of learners while modelling within the course. Thus the diagnostic dimension is stressed as very important in the course, because it gives a résumé and the possibility to apply all the competencies learned within the previous dimensions.

### **What you test is what you get! – First Results of the Pilot Study**

The test instrument was piloted in September 2018 in a modelling seminar with 17 prospecting secondary teachers at university in their third semester. This course was a blocked seminar with four sessions each three hours. Between the third and fourth session, the students taught their developed modelling lesson in school and observed learners during modelling activities. The pre-test was done at the beginning of the first session and the post-test at the end of the fourth and last day of the course. In contrary to the first test version with open items, the new test time was now 25 minutes. All participants already had basic knowledge about mathematical modelling from one lecture in the first semester within the lecture-series with the topic “Introduction in Mathematics Education”. In this lecture the university students learn about the modelling cycle and they also solve a modelling problem. However, only basics about modelling are stressed in this lecture and of course one goal of introducing modelling in this lecture-series is that the prospective teachers are interested to choose a modelling course in the upcoming semesters.

Due to the fact that  $n=17$  is a very small sample in the current pilot study, however, the very first results are promising concerning the quality of the items and  $\alpha$ -values. Thus for the upcoming testing in the winter term with a larger population, the test instrument will be checked and if needed, modified again. In the following descriptive analysis the results of the pre- and post-tests are presented. The results are based on a dichotomy coding procedure, showing the means of the dimensions before and after the treatment. Because of the fact that  $n$  is smaller than 21, a test of Gaussian distribution was necessary. Not all scales had Gaussian distribution and in order to test the level of significance, the Wilcoxon-Rank test (Bortz et al., 2010) was necessary. In Figure 5 the significance values become evident:

**Figure 5: Results of pre- and post-test**

The results show statistically significant differences after the treatment for three of the dimensions. Although no significance value could be stated for the instruction dimension, an increase of teaching competencies becomes evident like for the rest of the dimensions as well. The modelling course as the dependent variable can be seen as an effective predictor, so that teaching competencies for mathematical modelling increase. The mean of several items also makes clear that the treatment and thus the structure and content of the modelling course focuses on the central aspects of teaching and learning mathematical modelling. The last item within the Theoretical Dimension for example shows two tasks and one has to decide, which of them is a modelling problem. This item could also be put in the Task Dimension, but in this case, this item focuses more on the question of what mathematical modelling means and what characterizes it. In the pre-test the mean was 0.65 and in the post-test 1.00. Although students had basic pre-knowledge about modelling, it was not a trivial question at the beginning. During the modelling course, the university students again recognized several criteria of (good) modelling problems and that a real context leads not automatically to the conclusion that one can speak of a modelling task.

The Diagnostic Dimension contains many items for testing the declarative knowledge. As described in the previous section, items were developed, which show a short conversation of learners working on a modelling problem. One right answer had to be chosen according to the modelling phase the learners in the presented scene worked primarily. An increase of the means becomes visible from pre to the post-test from 0.65 to 0.88 for such a diagnostic item or from 0.41 to 0.71 for a similar item. Beneath this testing, the university students also evaluated the course separately, which is a normal procedure in my seminars. The aspect of the Theory-Practice-Balance is always strongly emphasized from the prospective teachers (see Borromeo Ferri, 2018). In particular the development of an own modelling problem and teaching this at school is for most of the students crucial for understanding the nature of mathematical modelling.

## Summary, Discussion and Outlook

The model of teaching competencies for mathematical modelling is based on a long-termed Design-based research approach. Until now a test instrument for the four teaching dimensions did not exist in order to assess the increase of these competencies in a modelling course by using a pre- and post-test design. In fact it became evident that a test instrument with open items offered a great insight into prospective math teachers thinking concerning their knowledge about mathematical modelling, but it was difficult to evaluate and the test time was too long. The goal was to develop items and scales in order to grasp each of the teaching dimension by reducing the test time.

The presented results are only based on a pilot-study with a small population of students and thus no generalization is possible at this time. However the results allowed an insight into the quality of the items on the one hand and on the other hand statistically significant differences can be stated for three of the four dimension concerning an increase of the teaching competencies on a descriptive level. The pilot study focuses on the test instrument and also on the course as a dependent variable with the hypothesis that prospective teachers, who participate in this seminar, get an increase of their teaching competencies. Hence, a control group is needed. These university students could attend for example a seminar on mathematical problem solving. Then both groups can be compared and a further hypothesis is that mathematical modelling needs more specific teaching competencies than mathematical problem solving, although both topics are very close. Definitely it is clear that the sample size must be enlarged anyway, in order to guarantee the reliability of the test instrument.

Normally the goal of a developed test instrument is that it is universally applicable. The test of modelling competency from Haines and Crouch is such an example. The idea of developing tasks for the sub-competencies of the modelling cycle was great and in the last decades, several researchers adapted these tasks for learners in secondary or high-school. That requires that learners at school or university students were taught in modelling in order to assess them. The same idea is behind the test instrument for the four dimensions of teaching competencies. You can only get what you test, when the contents of the modelling course are in line with the test items, if you want to measure for example an increase of these competencies. This means that the test instrument can, in principle, be used worldwide, but it will certainly work best if the contents of the modelling courses are very close to the one presented here. This is also a big limitation for this test instrument at this stage, but the goal is to use this test instrument together with colleagues from Germany and further countries in order to see if a transfer is possible.

# On the positive influence of product-orientation in mathematical modeling: A research proposal

Wolfgang Bock<sup>1</sup>, Martin Bracke<sup>1</sup>, Patrick Capraro<sup>1</sup> and Jean-Marie Lantau<sup>1</sup>

Technische Universität Kaiserslautern, Germany; [bracke@mathematik.uni-kl.de](mailto:bracke@mathematik.uni-kl.de)

*Keywords: Product-orientation, modeling, best-practice examples.*

## Motivation

The term *mathematical modeling* as we have observed in 25 years of modeling projects (Bock & Bracke, 2015), bears for many students and teachers the notion of something visible and touchable. In our opinion mathematical modeling can and has to be considered in a broader fashion, also allowing what Blum and Leiss (2007) call a mathematical model, namely the mathematical description of a real process. Experts in applied mathematics, i.e. scientists working with mathematical modeling, however describe the necessity of an *end product* to be presented as solving a client's problem in a suitable way (see Neunzert & Prätzel-Wolters, 2015), like a real prototype made from metal or plastic or developing a software or a process simulation, all based on the mathematical model. In the last CERME, Bock, Bracke, and Capraro (2017) defined the term product, closely related to the notion given in economics or marketing:

## Definition

*In a mathematical modeling situation (with an authentic and real-world problem) a product is a deliverable in the language of the client which satisfies the needs incorporated in the task given by the client to the provider in such a way that the client can use it directly for his purposes.*

Based on former modeling week reports since 1993, Bock, Bracke, and Capraro (2017) proposed a second cycle within the modeling cycle based on client interaction. This poster is an outline for our future research, i.e. the analysis of the positive influence of product-orientation in mathematical modeling processes.

## Best-practice examples for product-orientation in modeling

During different modeling activities (Bock & Bracke, 2015) a positive influence of product-orientation for the motivation and the quality of the mathematical modeling process was observed in contrast to projects without product orientation. Recently several product-oriented modeling activities have been carried out (Lantau & Bracke, 2019; Lantau, Bracke, Bock, & Capraro, 2017). During a modeling week (3.5 full days + 1 day for presentations), 5 students of Grades 11 and 12 were asked to build a 3d scanner. They were provided with electronical devices and components, such as *Raspberry Pis*, microcontrollers, sensors, etc. The students handled electric circuits and learned to control the stepper motor, the sensors and data processing. As the construction is mainly a problem of electrical engineering and programming, the data processing contains many mathematical questions. In fact it is impossible to build a working device without having a good mathematical model and awareness of the mathematical toolbox! Due to the project-orientation however, mathematical difficulties had no need to be pointed out explicitly, since the product itself is going to raise the right questions.

## Research questions

A positive influence of product-orientation in mathematical modeling has been observed. The next step is to analyze this fact both in an empirical as well as in a theoretical way. The aims are: 1. *To model and understand the underlying processes*; 2. *To analyze the influence of product-orientation on students' learning processes*; 3. *To analyze the influence of product-orientation on the quality of results*; 4. *To develop new methods for interventions and guidance in mathematical modeling*. For this we plan to analyze several product-oriented, long-term modeling projects. We are going to use videotaping, questionnaires, interviews. Moreover we plan to analyze of the modeling processes using a new model of dynamical network graphs. Finally, it will be important to create and study adequate forms of teacher training suitable to train teachers in creating and supervising product-oriented modeling projects. First steps have already been undertaken (cf. Lantau & Bracke, 2019; Bock, Bracke, & Capraro, 2019; Lantau, Bracke, Bock, & Capraro, 2017).

# Comprehending mathematical problem texts – Fostering subject-specific reading strategies for creating mental text representations

Jennifer Dröse

TU Dortmund University, Germany; [jennifer.droese@math.tu-dortmund.de](mailto:jennifer.droese@math.tu-dortmund.de)

*The comprehension of mathematical problem texts has been identified as one of the essential steps towards solving modelling problems successfully. Understanding in this context means constructing an adequate situation model by using reading and understanding strategies. A separate strategy training might foster those strategies as studies indicate. Therefore, the presented study reports on a design research project with the aim of fostering subject-specific reading and comprehension strategies. Presented are further specifications of the processes of constructing mental text representations as well as insights into the use of strategies. The case study indicates that the fostered strategies contribute to different steps in the process of constructing mental text representations. Those strategies seem to be constantly used by the students to deal with word problems within the teaching-learning arrangement and might therefore be relevant for modelling processes in general.*

*Keywords: Situation model, mental text representations, subject-specific reading strategies, strategy training, comprehending mathematical problem texts.*

## Introduction

“Understanding the content of a task is fundamental for solving it (...)” (Leiß, Schukajlow, Blum, Messner, & Pekrun, 2010, p. 123). There is a wide range of mathematical tasks used to link or apply mathematical models, concepts and procedures to reality, ranging from simple word problems to complex modelling problems. Greefrath and Vorhölter (2016) categorize different accesses to mathematical modelling referring to Griesel (2005) when describing the term modelling in general as “the process of developing a model based on an application problem and using it to solve the problem” (Greefrath & Vorhölter, 2016, p. 8). Many kinds of those application problems are presented to the students in text format. This requires reading and understanding the problem text as the basic step in the modelling and solution process (Plath & Leiß, 2018). Understanding a text in general and a (modelling or word) problem text specifically goes along with understanding the described situation, i.e. constructing an adequate situation model (Leiß et al., 2010; Tapiero 2007; Weimer, Reusser, Cummins, & Kintsch, 1988). As Leiß et al., (2010) point out precisely the step of constructing a situation model is one of the most challenging ones in mathematical modelling. Reasons for difficulties in modelling and word problem solution processes have been hypothesized to lie in “a lack of strategic understanding both of the language involved and of the situation denoted by its verbal description” (Reusser, 1987, p. 474). Furthermore, Leiß et al. (2010, p. 119) point out: “strategies for constructing an adequate situation model have a significant influence on the modelling competence.” Meanwhile, there are indications that the use of these strategies can be trained separately (Leiß et al., 2010). Therefore, specific teaching-learning arrangements for fostering students’ reading strategies are required as a first step towards fostering modelling competencies in general. The presented study reports on a design research project in which a teaching-learning arrangement was iteratively developed and investigated, that aims at fostering subject-specific reading strategies for fifth graders

by using strategic scaffolding (Prediger & Krägeloh, 2015). So, following the distinction of Blomhøj and Bergman Ärleback (2018) on research in the field of modelling and application, this project can be located within the development, implementation and evaluation of a specific aspect of modelling activities (namely fostering understanding strategies for constructing a situation model).

After further specifying the theoretical background of generating a situation model in the following section, the methodological framework and empirical insights are presented.

## Theoretical Background

### Mental text representations as units of understanding

There exists a wide consensus within reading theories that during reading processes (of mathematical problems) four text representations are to be mentally constructed (Tapiero, 2007, Kintsch, & Greeno, 1985; Reusser 1987): the representation of (1) the text-surface, (2) the propositional structure, (3) the situation described in the text and (4) the problem. The term *mental text representations* resumes those four kinds of representations. Steps towards constructing those representations have also been included in different conceptualizations and models describing modelling processes (cf. modelling cycle by Blum and Leiß, further illustrated in Leiß et al., 2010) or solution processes of mathematical word problems (see Reusser, 1987). As different terms have been allocated to those four representations, their characteristics are briefly outlined with reference to Reusser's model for treating word problems (1987), which is chosen due to its focus on reading and comprehension processes.

- (1) The *representation of the text-surface* (not directly displayed in the model) is mainly the representation of the surface structure, text order, syntax and wording of the text (Tapiero, 2007). Only directly expressed propositions are represented here (Kintsch & van Dijk, 1978).
- (2) The *representation of the propositional structure* (named *text base* in Reusser's model) is a coherent text representation constructed by forming and organizing propositional units into a global structure (Kintsch & Greeno, 1985).
- (3) In the *representation of the situation* (named *situation model*), the information given by the text are integrated with the readers' prior knowledge or goals (Kintsch & Greeno, 1985) to make inferences of different kinds (drawn from text or prior knowledge) (Weimer et al., 1988). Reusser (1989) therefore defines the situation model as "the personal cognitive structure to which the process of understanding is directed. The situation model is the cognitive correlate to the situation structure either supposed from the author's point of view or understood from the reader's point of view" (Reusser 1989, p. 136ff., translated by Plath & Leiß, 2018, p. 161).
- (4) The *representation of the problem* (named *problem model* in Reusser's model) is an extension of the situation model focussing especially on the aspect of the goal (generated or given problem question) guiding the construction process (Kintsch & Greeno, 1985; Reusser, 1987).

As stated above, for mathematical modelling tasks, the process of constructing a situation model is the most challenging one (Leiß et al., 2010). Meanwhile, most of the mathematical problem texts examined by researchers are restricted to one mathematical relation mathematized in one step (c.f. Reusser, 1987). Therefore, they do not further specify the process of building situational or problem representations (Kintsch & van Dijk, 1978). As many applied mathematical problem texts display

more than one relation and multiple steps, the model needs to be differentiated to take the processes of constructing mental text representations into consideration (Prediger & Krägeloh, 2015).

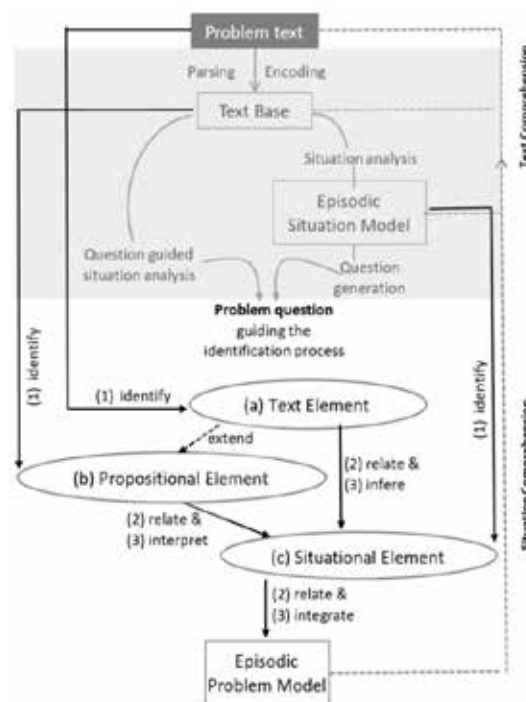

### Processes of constructing mental text representations

Considering the situational or problem representation of multi-step problems, different mental elements must be related to each other. In line with Schnotz (1994), these mental elements form the basic units of the writer's and the reader's communication process: (A) the *writer* identifies the relevant units of the mental representation, constructs an adequate language representation for each of them and integrates them into a text, (B) after that, the *reader* needs to identify the relevant textual or language units, interpret their meaning and integrate them into a mental representation (Schnotz, 1994). In order to include these considerations into Reusser's model, the model is extended as shown in Figure 1 in order to capture the reader's processes of achieving local or global coherence. The detailed specification of the reader's activities and processes are integrated. Following from the investigation of Weimer et al. (1988): (1) relevant elements have to be *identified*, (2) elements have to be *structured* and *related* and (3) elements have to be *interpreted* and new elements have to be *inferred* (see Figure 1). Apart from these processes, the kinds of mental elements are further specified. Those relevant mental elements can be of (a) *textual*, (b) *propositional* or (c) *situational* type. At first, the (a) *text elements* and (b) *propositional elements* have to be (1) *identified* from the problem text or the text base, according to the problem question. Afterwards, (a) *text* and (b) *propositional elements* can be (2) *related* to (3) *interpret* or (3) *infer* new (c) *situational elements* that have not been identified before. Then those (c) *situational elements* can be (3) *related* and (3) *integrated* to form the problem model (see Figure 1).

These kinds of processes of text comprehension are initiated and monitored by *reading strategies* (Tapiero, 2007; Leiß et al., 2010). Whereas the steps in the model themselves cannot be taught directly, reading strategies can be fostered in separate strategy trainings (Leiß et al., 2010). Most relevant for the texts in view are the comprehension strategies identified by Prediger and Krägeloh (2015, p. 951):

- (S1) Focus on the question to find relevant information
- (S2) Focus on the information together with their meaning
- (S3) Focus on relations connecting the information

Reusser (1987) indicates that strategies might support special processes in his model. One might consider that the named strategies can be linked to the processes as follows: S1 to the process of

**Figure 1: Extended model for treating word problems (adapted from Reusser, 1997; Prediger & Krägeloh, 2015)**

question generation and (1) *identifying* elements, S2 to the process of (1) *identifying* elements and S3 to the process of (2) *relating* elements (see Figure 1). However, further investigations are required on how these strategies can support the displayed processes to construct a situation or problem model and how the use of strategies might differ when dealing with different problem texts. For considering those research aspects and getting first insights, the focus is laid on word problems where the construction of the mental text representations is the main aim rather than on rich modelling tasks, which require additional processes after understanding the problem text.

### **Research demands and questions**

The considerations described above called for designing a teaching-learning arrangement to foster students' comprehension strategies. The corresponding qualitative analysis of the initiated comprehension processes pursued two research questions:

- (RQ1) How can the three comprehension Strategies S1, S2, S3 contribute to students' mental construction processes described in the extended model for treating word problems?
- (RQ2) How do students' use of strategies differ for different word problems?

### **Methodology of the design research study**

*Design research as methodological framework.* Due to the dual aims of designing a teaching-learning arrangement to foster students' use of subject-specific reading strategies as well as describing and analyzing the use of comprehension strategies, which is in line with the considerations by Blomhøj and Bergman Ärleback (2018) concerning theory-practice relations, the framework of topic specific design research has been chosen. It iteratively connects (1) the specification and structuring of the learning content, (2) the creation of the teaching-learning arrangement, (3) the use of the teaching-learning arrangement in design experiments, which are afterwards analyzed to (4) generate contributions to local theories on the learning content and learning processes (Prediger & Zwetschler, 2013).

*Design experiments as a method for data collection.* In the presented study, six design research cycles have been conducted, five in laboratory setting with 2-3 students each and the last one in a classroom setting. Each cycle consisted of approx. 4-7 sessions of 90 minutes each. This paper focuses on Cycle 5 in which six pairs of students have worked on the teaching-learning arrangement (in total 4320 minutes of video data).

*Methods of qualitative data analysis.* For the qualitative data analysis, a category-led deductive procedure has been chosen. The use of strategies has been coded (according to a categorical scheme presented in Dröse and Prediger (in press)). Afterwards, the moments in which the use of strategy was identified, have been categorized with respect to the processes of *identifying text, situation* or *propositional elements*; *inferring situational elements* or *relating* mental elements (see Figure 1). Here, the case study of Metin and Yaren (both boys are 11 years old and attend a secondary school in a German urban area) is presented, based on 120 minutes of video data (partly transcribed).

## Empirical insights: Yaren's and Metin's construction of mental representations

The case of Yaren and Metin provides an insight into their process of constructing mental text representations and their use of Strategies S1–S3 concerning RQ1. The two boys work on Task 3 “Bear child” (Fig. 2) in Sequence 1 and on Task 5 “Parrot feeding” (Fig. 3) in Sequence 2.

### Bear child

The brown bear child in the zoo weighted 700g at his birth. After his birth it lost 200g because it was ill. Over the last weeks, his weight has increased by 4000g and it is healthy again.

How much does the brown bear child weight now?

Figure 2: Task 3

### Parrot Feeding

In the zoo, the children are feeding the parrots. Felix fills parrot Tobi's bowl with 10g sunflower kernels and 15g berries. In the bowl, there have already been 3g feed before the feeding. Parrot Piet eats 5g of parrot Tobi's feed.

How much feed does parrot Tobi have in the end?

Figure 3: Task 5

## Sequence 1: Inferring implicit situational elements in Task 3

At the beginning of Sequence 1, Metin and Yaren have already *identified* the relevant *text elements* and have written them down on three cards. Metin now tries to express the relations between those elements to *infer* the needed *situational elements* as well as the problem model.

- 1 Metin: Yaren look, at first he has weighted 700g [*puts down the card on which he had written the text element weighted 700 g*], then he got down to 200g [*points at the corresponding second card*], later to 4000g [*points at the third card*].

Metin's explanation reveals an inappropriate *problem model*. This could be either (1) due to a lack of understanding of the propositional structure of the individual *text elements* or (2) due to the fact that he relates the elements to each other by interpreting them as fixed states rather than considering other relationships. Afterwards, Metin tries to organize the information in a concept map.

- 101 Teacher: If I understood correctly, you wanted to start with 700. What happens then? (...)
- 102 Metin: Yes, 200g, because he loses 200g. And then later rises to 4000g. [*connects the two element cards with an arrow, see Figure 4*]
- 104 Teacher: So, he weighted 700g at his birth, then he loses 200g, then this was 4000g altogether. Does that fit?
- 105 Metin: Yes, that fits (...)
- 107 Metin: or if, wait look, if he loses 200g of 700g, then that would be 500g, so then this have to be 4500g?

Figure 4: Metin's concept map of the situation

When the teacher verbalizes the relation that Metin has visualized (l. 104), Metin implicitly *infers* the two *situational elements*, “state after the bear was ill” and “state now that the bear is healthy again” (l. 107) that are not explicitly mentioned in the problem text. After finishing his visualization with cards and arrows, Yaren explicitly describes the relation between the two states implicitly mentioned above (l. 206).

- 206 Yaren: (...) It has weighted 500g and then it got healthy and got 4000g, because it was healthy afterwards (...).

Regarding RQ1 the sequence gives an example for a pattern we have often found in the data: When students activate the Strategies S2 (focus on meaning of information) and S3 (focus on relation of information) as triggered here by the cards and arrows, they can *identify* not only *text elements*, but *infer* also further *situational elements* and create an appropriate *situation and problem representation*.

### Sequence 2: Expressing relationships between identified and inferred elements in Task 5

After solving Task 3 and 4, Metin and Yaren work on Task 5 “Parrot feeding” (Figure 3). At first, they write down the relevant *text elements*, and then the teacher asks them to express the given relations.

- 1 Teacher: Tell me, what happens to the 10g and the 15g in the task? What about them? (...)
- 3 Metin: So at first, there were 10g sunflower kernels, then 15g berries and then he has eaten 5g of Parrot Piet’s feed.
- 4 Yaren: (...) Ah yes, then there were 20g left.
- 5 Metin: (...) Ah so (...) now I understand (...) I found the result. He had 25g in total [points at the cards and arrows] and then (...)

When being asked to articulate the actions taking place in the task, Metin uses the Strategies S2 (focus on meaning) and S3 (focus on relations). He puts the given information into the described order to symbolize the relation between the *text elements* (l. 3) and the inferred *situational elements* (l. 5). Yaren explains that there are only 20g left (l. 4). The teacher points to one information that has already been written down but not used, so far:

- 101 Teacher: Okay and now, you have one card left written 3g on it. Do you need this?
- 102 Metin: No, not really... but [is reading the text]. Yes, we can use it, because (...)
- 108 Metin: Ah, Felix has given him something and he has had 3g before.

Metin’s explanation reveals that he has focused on the meaning of the 3g first (S2) and then tries to relate the *text element* to the information already given (S3). In this sequence, the teacher is not expressing the relation among *elements* herself as she has done in Task 3; instead, first she prompts the students to do so (l. 1). Later on, she prompts the students to take the meaning of the *text element* into consideration (l. 101). Being familiar with the scaffold, the boys use Strategies S2 and S3 to *relate* mental elements and the teacher’s prompt for activating S2 suffices to activate S3 as well (l. 108). Concerning RQ1, this shows how both strategies are intertwined in the process of *relating* elements. This observation reoccurred in further data.

### Overview of used strategies to construct and process mental elements

Concerning RQ2, Table 1 gives a short overview on the strategies, which Metin and Yaren used to construct mental elements. For each task, the relevant *text* and *situational elements* as well as the relations between them have been specified. For the Tasks 3 – 5 those *text elements* can be either the starting point or a change of the situation (Change 1, Change 2), as described in the problem text. The *situational elements*, that have to be *inferred*, can be the state of the situation either after the first or after the second described change (State 2, State 3). After specifying the relevant mental elements, the coded strategies (S1 – S3) were assigned to the prevailing mental elements, when the strategies

are used before a successful *identification*, *inference* or *relation* of this mental element. The use of those strategies is displayed in Table 1 without focusing on its frequency or its order.

Identified/ Inferred/ Combined Elements:	Task 3 (solved together)		Task 4 (solved separately)		Task 5 (solved together)	
	Metin	Yaren	Metin	Yaren	Metin	Yaren
Identify problem question	S1, S2		S1	S1	S1	
Identify Text element 1: Starting point	S2	S1, S2, S3	S2	S2	S2, S3	S2
Identify Text element 2: Change 1	S2	S3	S2	S2	S2	S1, S2
Identify Text element 3: Change 2	S2	S2	S2	S1, S2	S2	S2
Construct Situation element 1: State 2	<del>S1, S2, S3</del> , S1, S2, S3	S2, S3	S3	S2, S3	S2, S3	
Construct Situation element 2: State 3				S2	S2, S3	
Relate Element 1, 2 and State 2	S1, S2, S3	S1, S2, S3	<del>S2, S3</del> , S3	<del>S2-S2</del> , <del>S3-S3</del>	<del>S2, S3</del> , S2, S3	
Relate Element 2, 3 and State 3	<del>S1, S2</del> , S2, S3	S3, <del>S2, S3</del> , S3	<del>S2, S2</del> , <del>S3-S3</del>	<del>S2-S3</del> , S3	S2, S3	<del>S2</del>

**Table 1: Strategies used to assimilate elements of different kinds** (~~S3~~-represents unsuccessful strategy use)

For answering RQ2 the following differences and similarities in the use of strategies can be observed: The analysis of Table 1 reveals that both boys use Strategy S2 to *identify* relevant *text elements*, having also focused on the question (S1). Furthermore, in Task 3 all strategies are used to *infer* and *relate* mental elements, while in Task 4 or Task 5 mainly Strategies S2 and S3 are used. This underlines the close entanglement of those strategies. With regard to RQ2 the boys' use of the identified strategies seems to become more stable with frequent use of the scaffold.

## Discussion and outlook

The case study of Metin and Yaren provides first insights into the use of the fostered strategies to *identify*, *infer* and *relate* mental elements. The analysis reveals the contribution of the identified strategies to the *inference* of implicit situational elements (Sequence 1) and the processing of *relations* between these elements (Sequence 2). Furthermore, the importance of the interplay between Strategies S2 (focus on meaning) and S3 (focus on relations) can be lined out (RQ1). The use of strategies to *identify*, *infer* or *relate* the prevailing mental elements seems to become more stable during the process of task comprehension (RQ2).

These results are of particular interest for research on modelling against the backdrop of difficulties in constructing a situation model (Leiß et al., 2010). Therefore, two indications might follow from the empirical insights: (1) as the strategies named above might contribute to generating a situation model it is possible that those strategies belong to the strategies having an impact on modeling competencies (see Leiß et al., 2010), (2) the use of those strategies might be fostered by strategic scaffolding and their use seems to become more stable independent of the tasks' characteristics. So, the use of those strategies might be extended to rich modelling tasks – presented in written format and with more than one relation described – to facilitate the understanding of the situation.

The presented study is limited at first because of the small number of students that have been analyzed as well as the laboratory setting in which the research was conducted. Further research needs to extend the investigation of the use of strategy to more students and different problem texts. It should especially take the interplay between the named strategies as well as between the teacher and students

into consideration. At least the investigation of reading strategies might be extended from fostering reading strategies for word problems to reading strategies for modelling problems.

## Acknowledgment

The study is conducted within the MuM-research group (mathematics learning in language diversity) in cooperation with the project Mastering Math funded by the Deutsche Telekom Foundation (2011-2020, grant holder Susanne Prediger and Christoph Selter).

# Mathematical modeling and the role of language proficiency

Sevinç Göksen-Zayim, Derk Pik, Rijkje Dekker and Carla van Boxtel

University of Amsterdam, The Netherlands;

**Keywords:** *Mathematical modeling, conceptualization, mathematization, language proficiency.*

## Theory

Modeling is defined as "a practical and creative process in which realistic problems are translated into mathematical form" (cTWO, 2007, p. 25). Usually, modeling problems in context-rich assignments are offered to learners through texts. One of the first obstacles students encounter is reading and interpreting text. In secondary school, being able to read a problem is a decisive factor in solving a problem (Korhonen, Linnanmäki, & Aunio, 2012). The language used at school often forms an obstacle to learning mathematics (Van Eerde & Hajer, 2009). It is thus to be expected that language is an important factor at the various phases of the modeling process, although the role of language proficiency may be different. To analyse the different difficulties concerning language, we have to split up the modeling process in different phases. According to Spandaw and Zwaneveld (2012), modeling encompasses various activities that are carried out consecutively, as shown in Figure 1.

**Figure 1: The modeling cycle (Spandaw & Zwaneveld, 2012, p. 240)**

Language proficiency may play a different role in every phase of the modeling cycle. The phases are indicated by:

The phase of conceptualizing: the student is able to understand the text in which the problem is posed in order to make the translation into a conceptual model.

The phases of mathematization and solving: the student goes from the conceptual model to the mathematical model. Then the student will try to solve the problem. Mathematical reasoning occurs in both of these phases.

The phase of interpretation: translating the mathematical model into reality appeals to language skills. This skill is similar, but inverse to the language proficiency in the conceptualization phase.

Mathematical modeling is absent in the greater part of lower secondary education in the Netherlands. For that reason, this study will emphasize modeling in lower secondary education. This study will answer the following research question: *Which language problems occur in the three phases of mathematical modeling in context-rich assignments?*

## Method

Participants of the study are students from grade six, eight and ten. These students are 11 up to 15 years and participated from four primary schools and four secondary schools located in an urban environment. 260 students performed two mathematical modeling tasks. The first modeling task is directed towards algebra and the other towards geometry. Each individual task consists of two parts. The first part is a modeling assignment in a rich context and the second assignment is a mathematical core assignment, focusing on the mathematical content without context. In consultation with the teacher of each participating class we selected two students ( $n=26$ ), one with strong language proficiency and the other with weak language proficiency, with whom we performed a task based interview. Six teachers were interviewed about the levels of the designed modeling tasks. 12 students (two from each class, from 11 up to 15 years) were asked to do the assignment while thinking aloud.

## Results

The analyses of students' answers, the task based interviews and the think-aloud protocols showed that language is an important obstacle, especially in the conceptualization phase. In all grades most of the students repeatedly reread the text of the modeling task. In many cases learners fail to construct a meaningful representation of the described situation. The transition from reality presented by the text towards a conceptual model often halts halfway. The outcome of the students' answers for the geometry modeling task did not show big differences between the rich context part and the mathematical core part, for all three grades. From the outcome of the task-based interviews with the learners, feasible components and levels for the different modeling phases are formulated. The think-aloud sessions gave more insight in the language problems students encounter while solving the modeling task and showed the strategy that students use.

# Pre-service mathematics teachers' learning through designing modelling tasks

Carolina Guerrero-Ortiz<sup>1</sup>

<sup>1</sup>Pontificia Universidad Católica de Valparaíso, Chile; c\_cguerrero@yahoo.com.mx

*The results of analysing the projects for the teaching of mathematics and modelling developed by future mathematics teachers are discussed in this paper. The participants were part of a seminar in which the objective was to develop their mathematical and pedagogical content knowledge related to the teaching of mathematics through the design of modelling tasks. With a qualitative methodology the written reports of and interviews with the pre-service teachers were analysed. The results bring to light some elements associated with their knowledge and how this knowledge is constructed in their experience with modelling activities and then reflected in the creation of teaching tasks.*

*Keywords: Modelling task, future teachers, teacher training.*

## Introduction

The design of novel tasks and teaching activities represents a challenge for teachers and future teachers. They must be able to involve students in meaningful activities and create environments in which students construct and reflect on their own learning. In designing modelling tasks, the future teachers' knowledge about the context and the mathematics related to it, joined with the knowledge about the teaching and learning of the students becomes structured and shapes the tasks. The design and implementation of modelling tasks has been subject of innumerable studies with attention to the characteristics of the final product; but few investigations consider the processes that are favoured in this activity (Czocher, 2017), for example the construction of the teacher's pedagogical content knowledge.

When modelling activities are introduced to the classroom, teachers must adopt an adaptive view of new teaching methods. This involves a challenge that requires the mastery of mathematical knowledge associated with the context of the task and adapting that knowledge to the environment in which students will work with the task according to the learning objectives (Doerr & English, 2006). In the setting of a teachers' training seminar, we analyse: 1) how future teachers, when designing teaching tasks, construct and transform their mathematical knowledge associated with the modelling of population growth and 2) how this knowledge is adapted for teaching in a middle school mathematics course. The research question is: *What elements associated with pedagogical content knowledge emerge in the design of modelling tasks for teaching mathematics?* An important aspect in this study is the design process where participants learn to model to teach modelling. This fact is evidenced in the exploration of several situations and in how future teachers simplify and idealise the initial situations to adapt the task to the knowledge of the students.

## Conceptual framework

When studying task design in mathematics education two perspectives can be identified: the design as implementation or the design as intention. The task design analysed here is characterized as

design as intention since it addresses the initial formulation of the design (Czocher, 2017) and the analysis is supported by constructs for studying teacher's pedagogical content knowledge (Ball, Thames, & Phelps, 2008; Doerr & English, 2006; Carrillo-Yañez et al., 2018). By teaching modelling it is intended that teachers become competent at modelling activities, they also should be able to link knowledge about modelling cycles, about goals and about types of tasks. Solving, analysing and creating tasks as well as planning and performing modelling lessons are important aspects here (Borromeo Ferri & Blum, 2010; Huincahue-Arcos, Borromeo Ferri, & Mena-Lorca, 2018). Designing and modifying tasks to be easier or harder for presenting mathematical ideas constitutes a part of the teacher's knowledge (Ball, Thames, & Phelps, 2008). When designing tasks for learning mathematics and modelling, the teacher's pedagogical content knowledge comes into play in teaching organization, in the understanding of how to present the concepts to favour learning and when understanding the mistakes associated with the domain (Doerr & English, 2006). In addition, the teacher must know the specifications of the curriculum and maintain a critical position to organize the learning and management the class (Carrillo-Yañez et al., 2018). The practice of modelling leads to the development of modelling skills (Blomhøj & Kjeldsen, 2006), so that when the teachers design a task, they structure their specialized content knowledge related to models with the intended knowledge for the students. On the other hand, when modelling students build knowledge depending on the characteristics and cognitive demands of the tasks (Henningsen & Stein, 1997). Therefore, it is expected that the tasks created by future teachers support progress in the modelling abilities of the students. According to the model of three dimensions (Blomhøj & Kjeldsen, 2006), the modelling competences can be distinguished as: (1) Technical level, related to the kind of mathematics the students use and to how flexible they are in their use of mathematics. (2) Radius of action, related to the domain of situations in which students can perform modelling activities and (3) Degree of coverage, according to the phase of the modelling process the students are working in, and the level of their reflections.

## Context and method

In most Chilean teacher training programs, modelling has not been explicitly part of the education for future teachers. The future teachers take part in several courses of mathematics, didactics and pedagogy. They learn mathematical concepts and theories of education, but they have few experiences with modelling situations; as Blomhøj and Kjeldsen (2006) pointed out modelling is different than the nature of mathematics. In this context, it is described and analysed the process developed by a group of pedagogy in mathematics students, when they designed an activity for teaching. The experimentation was carried out with a group of six students, who participated in a research seminar for future teachers. Here, the case of a group with two participants is presented. They were selected because of their willingness to participate in the research. In the seminar some topics of differential (and integral) calculus and differential equations were discussed and among these functions, derivatives, logistic equations and systems of differential equations. Some perspectives of modelling (Blomhøj & Kjeldsen, 2006; Borromeo Ferri, 2006) were also reviewed. During the seminar several discussions about the use of technology and the content knowledge for teaching (Ball, Thames, & Phelps, 2008) were carried out. The students explored modelling different phenomena and proposed a teaching activity for middle school level (15 years old). The

process of designing a task (for approximately three months) was documented, where participants studied how some growth situations are described in reality. Then, after simplifications and idealizations their initial study took shape of a teaching activity. The design phase considered aspects such as, idealization and exploration of the initial conditions, parameter values and the domain of the solutions. Meetings with students once a week during one semester were developed in where the design process was followed. At the end of the course, they presented the teaching task and a description of the process of designing it in a written report.

Data analysis was carried out following a qualitative perspective (Cohen & Manion, 1989). First the episodes related to the modelling phases along the process of designing the task were identified. Then, units of meaning associated with mathematics, modelling and pedagogical content knowledge were identified. At the end of the seminar participants were interviewed by two researchers to verify the first interpretations of the author. Finally, the units of analysis identified in the written report and those from the interview were contrasted and discussed in the modelling seminar, where the author took part. Thereby, the validity of the results was verified.

## **Discussion and analysis of results**

In this section, the study carried out by the participants related to the phenomenon in question is initially presented. It is not the intention in this paper to inform about a common process of population growth modelling, however, in order to analyse the knowledge that emerges when future teachers design a modelling task, we present a summary of the facts that they recognise as relevant. It should be noted that most researches on teacher's knowledge do not explicitly address the role of modelling (Ball, Thames, & Phelps, 2008; Carrillo-Yañez et al., 2018) but consider it as an element of mathematical practice. Here modelling is posed as a precursor element of the development of future teachers' knowledge. Furthermore, the experiences with modelling activities can be related to the improvement of the mathematical knowledge of the future teachers. Subsequently the teaching task proposed by the participants was analysed where some elements from the pre-service mathematics teachers' pedagogical content knowledge were identified. Three episodes were recognized: first when participants explored the growth of penguin populations reported by the research literature, where the case was analysed by statistical methods. Second, when the relevant information was identified and linked with an idealised mathematical model. Third, when information gathered in the first and second episodes was adapted to create a task for teaching.

### **Study of real situation**

After consulting literature related to different growth phenomena, a growth situation of Magellanic penguins was selected (Pozzi et al., 2015; Valdebenito, 2013). The habitat places of this type of penguin were located on a map. In addition, the total population of penguins in the world was identified (1.5 million pairs of reproductive age). This led the future teachers to focus their attention on the population of penguins in Chile (700 pairs), particularly a population that is located on an ecological reserve that hosts around 400 specimens. Here participants observed the existence of infrastructure designed to allow tourism without affecting the reproduction of the penguins. This fact allowed them to transit from the study of a more general situation to the case of a growing population limited by a border. When doing the first exploration participants observed that studying

a population in freedom, implies considering predators and death of penguins due to the fishing process. By exploring the reproduction of the population, they identified the nesting seasons, the number of eggs per pair (2) and the places where the nests were located. They also noticed the existence of other predators like seagulls that attack eggs. Considering this information, participants associated the successful breeding with the number of chicks that survive per nest on each breeding season. These considerations were initially associated with logistic equations and systems of ordinary differential equations (predator-prey model).

Then, an idealisation of the situation was made, when participants saw the case as population growth in a limited place where the necessities of feeding (anchovies, sardines and some crustaceans) also influence the size of the population. Thereby, pre-service teachers made relationships between the competition for limited resources in the environment and the population size; this led them to model the situation using the logistic equation of population growth. The elements used to determine the parameter values in the equations were: the reproduction age (the females reproduce between 4 to 5 years old, while the males reproduce when they are 6-7 years old), and the penguins are monogamous. The average life expectancy is about 20 years. With this information students calculated an approximation of the growth rate.

This phase was a support for pre-service teachers to: a) recognise the reasons why some simplifications are necessary, b) recognise and explain the frequent difficulties students find in mathematizing a situation and c) identify and explain the behaviour of some situations. In addition to the ideas of Ball, Thames, and Phelps (2008) it is assumed that those elements must be part of the teacher's mathematical knowledge for teaching modelling.

### **Simplification of the real situation and modelling**

When simplifying the real situation, the participants made decisions that were reflected in the design of the task as will be discussed below. In summary, the literature gives information about the penguins' birth and mortality rates per year. Then by calculating an average students approximated this values by a constant (intrinsic rate of increase) to be used in the expressions to describe the population growth. From here, by comparing continuous and discrete exponential growth future teachers were aware of the complexity of modelling realistic situations. They also realised the limitations of modelling population growth with simple models. Hence, when pre-service teachers explored open modelling situations, they built their mathematical knowledge associated with the situation (Carrillo-Yañez et al., 2018), and when they used that knowledge to design the task, they strengthened their pedagogical content knowledge related to modelling practices (Doerr & English, 2006). Thus, the experience they got by exploring the characteristics of the phenomena served as the basis for the design of the teaching situation.

Below some of the arguments from the participants regarding to the relevant information and the simplification they made are shown:

Initial population – the literature mentions that in 1993 a population of 400 penguins was estimated in the reserve.

Birth- [...] paired penguins lay 1 to 2 eggs, but not all penguins are in pairs and not all couples get two eggs, for this reason the birth rate can be considered to be 50%. However not all chicks are born, which leads us to consider a birth rate of 40% of the total population. This rate is consistent with the data in the literature [...].

Mortality- [...] the longevity due to natural death of penguins is almost 20 years, in addition there are other factors that cause the death of this species [...], the spilled oil and the fishing nets, that add up to 16% mortality [literature information]. If [mortality] is adapted only to natural causes of death (Diseases, poisonings, etc.) an estimate of 14% can be made since the reserve has the necessary care to maintain the health of the penguins.

Predators- The presence of predators was not taken into account for the design of this task, since the penguins are in a reserve and are protected from these threats.

With this information the participants analysed two cases described by the equations  $\frac{dN}{dt} = kN$  y  $\frac{dN}{dt} = r\left(1 - \frac{N}{K}\right)N$ , getting the solutions  $N(t) = 400e^{kt}$  y  $N(t) = \frac{Ze^{rt}K}{Ze^{rt} + 1}$ . When studying the graphs of these expressions they identified the behaviour of a population modelled by the logistic equation and described it as below:

[...] if the population is less than the carrying capacity, the graph behaves increasingly, but when it approaches ( $K$ ) the graph begins to stabilise, instead if the population was greater than the capacity of load the graph behaves decreasingly and begins to stabilise when it is closer to  $K$ .

In this episode, stand out identification and simplification processes of relevant information and the participants' mathematical work using analytical and graphical representations. The experience gained studying the real situation helped future teachers to identify and anticipate appropriate mathematical representations to be used in the teaching activity. Those elements are related with the Specialized Content Knowledge (Ball, Thames, & Phelps, 2008).

### The teaching task

In this section the task designed by two participants is analysed. The learning objectives were defined as: Analysing the behaviour of a population based on birth and mortality rates in relation to the time. The task is the following:

In 1991 a massive death of penguins of the Magellanic species was evidenced. To revert the situation a group of people in 1993 decided to create a Natural Reserve of Magellanic Penguins called "Seno Otway". The reserve has capacity for hosting 6500 penguins. At the beginning the reserve started with an initial population of 300 Magellanic penguins. From a census they calculated a mortality rate of 70 per 500 penguins and a birth rate as 200 per 500 penguins.

Some of the questions that the future teachers posed are:

- 1) What do you think would happen if the population exceeds the capacity of the reserve?
- 2) Use the data for graphing the situation.

### 3) Analyse what should happen when reaching the load limit.

Those questions show that teachers focused on the carrying capacity as the relevant aspect that affects the growth of the population. The first question demands an intuitive answer from the students, with the third question they are challenged to prove or reject their initial conjecture by studying the data. To answer the second question, students were encouraged to organizing the data about the time and the population in a table, using this information they could build a graphical representation. Here, the future teachers' knowledge related to the different registers in which a mathematical content can be represented (Carrillo-Yañez et al., 2018) and their strength to interpret situations becomes evident. This is also related to the knowledge of some theories of learning as it is shown in the next fragment related to the characteristics of the task:

The activity is designed for the students to articulate the same information in different semiotic representations, and to look for a generality that represents the behaviour of the population [...]

The teachers' knowledge associated with the characteristics of modelling was also evident when they described the processes through which the student should transit when answering the questions. They anticipated that students would go through a spiral-shaped cycle increasing as they require more knowledge to answer the questions. This is shown in an extract of the written inform:

In order to solve successfully the task, it is necessary to carry out several modelling processes that respond to different situations, we could group the questions into three categories, easy (1, 2), medium (3, 4) and hard (5, 6); each of them corresponds to a separate modelling cycle that adds more difficulty as the students respond.

In the previous transcript the knowledge of pedagogical content was evidenced in the design of the task when teachers anticipated the students' reaction in relation to the difficulty in answering the items (Ball, Thames, & Phelps, 2008).

While designing the task, future teachers recognised the importance of students being aware of the idealization processes involved in the analysis of a phenomenon. In the following fragment, when justifying the pertinence of the question number three, they referred to the idealization that implies modelling the situation through the differential equation  $\frac{dN}{dt} = kN$  and compared it with the case

modelled by the equation  $\frac{dN}{dt} = r \left( 1 - \frac{N}{k} \right) N$ :

[...] the students should reflect on the exponential growth of the population, because so far we have only analysed an ideal case, where no carrying capacity or predators in the area have been taken into account.

In relation to the graphical representation of the behaviour of the population, future teachers pointed out that working with graphics could generate some errors of interpretation when students superficially see the generated curves; this is associated with the knowledge of the structure of mathematics (Carrillo-Yañez et al., 2018). They point it out as follows:

They [students] may build a more flattened exponential, arguing then that the growth population should be slower.

In the previous analysis a strong relationship between the (mathematical and extra-mathematical) knowledge constructed by future teachers when experiencing modelling to design a teaching task was observed. And the pedagogical content knowledge was evidenced when they were able to anticipate the students' actions with the modelling task. The task was designed to cross through the modelling cycle in different ways. However, the activity was subordinated to only working with the data in the tasks (Blomhøj & Kjeldsen, 2006).

## **Comments and conclusions**

It was evidenced that in the challenge of designing teaching tasks the future teachers experiment with mathematical and extra-mathematical knowledge and bring to light what they learn for planning the teaching. The future teachers' learning endured a transformation from studying pure mathematics to study the mathematical and extra-mathematical content associated with several phenomena. When exploring the situation, the participants' work highlighted activities as identifying relevant information, simplifying the situation, formulating a task, systematising, mathematising and analysing mathematically. Those activities reinforce their knowledge about the mathematical characteristics of the models. They also had the opportunity to link concepts, understand procedures, rules and meanings. The knowledge constructed in this way was a support for designing the task, so that it strengthens their pedagogical content knowledge. In relation to the progress of mathematical competence (Blomhøj & Kjeldsen, 2006), it was observed that the future teachers' performance with the modelling activity and the task designed by them are situated in the technical level, related to the use of mathematics and its representations. However, it is desirable that future teachers widen their radius of action.

The experience in this research showed that – in addition to the knowledge pointed out by Ball, Thames, and Phelps (2008) – for implementing modelling as a vehicle for teaching mathematics, the teacher should be able to: recognize the reasons why some simplifications are necessary, recognize and explain the frequent difficulties students find in mathematizing a situation, identify and explain the reasons for the behaviour of some situations, identify and anticipate appropriate mathematical representations, identify and enhance the transit through the different phases of a modelling process. On the other hand, some tension between developing modelling competences and teaching the content was identified. That is, although the task could be more open allowing students to build their own strategies, the final characteristics of the task limit the actions of the students to whom it will be directed. This situation has a strong relationship with the educational system because most institutions expect that teachers taught the content as it is described by the curriculum where modelling is considered closer to word problems. In the same way, Chilean teachers training programs are more directed toward the teaching of content rather than developing skills. Therefore, our challenge is to encourage pre-service teachers to explore innovative ways for teaching mathematics.

Finally, the construction of pedagogical and mathematical knowledge was analysed when pre-service teachers design a task; this fact does not allow us to know how future teachers put into play their pedagogical content knowledge in the practice. This aspect is been explored in parallel studies.

# Teachers learning to design and implement mathematical modelling activities through collaboration

Britta Eyriich Jessen

University of Copenhagen, Department of Science Education, Denmark; [britta.jessen@ind.ku.dk](mailto:britta.jessen@ind.ku.dk)

*In this paper, we present a model for upper secondary in-service teacher courses based on the Anthropological Theory of the Didactics and explore how we can teach teachers to design and implement mathematical modelling in their classrooms. The course evolves around Study and Research Path based teaching and strives to create para-didactic infrastructures as a framework for teachers' development of teaching practice. The novelty in this study is the sequence of shared preparation, observation and evaluation of teaching in the course. We describe the structures and their functioning through an example of a group of teachers' work. Based on the activity we discuss the potentials of creating such structures and the needs for further research in this field.*

*Keywords: Study and research paths, modelling activities, professional development, para-didactic infrastructures, upper secondary education.*

## Introduction

Throughout the years, several examples of in-service teacher courses on modelling have been presented with the purpose of supporting teachers to design modelling activities, promoting different theoretical approaches to mathematical modelling (Kjeldsen & Blomhøj, 2006; Doerr 2007; Blum & Borromeo Ferri, 2009; Barquero, Bosch, & Romo, 2018). These approaches have ways to engage students in modelling activities, where students sometimes choose strategies different from those foreseen by researchers or teachers. This is challenging for teachers, and might cause them not to implement new knowledge gained from in-service courses, professional development (PD) activities, in their teaching practices. García argues that PD initiatives require existence of structures supporting teachers while implementing more inquiry based teaching methods and he suggests lesson study or other versions of action research (García, 2013). According to Artigue and Blomhøj (2013), mathematical modelling can be regarded as one approach to inquiry-based teaching, which is why those supporting structures, mentioned by García (2013) should be implemented in PDs on mathematical modelling.

In this paper, we present the result of a pilot study, where upper secondary in-service teachers were taught to design mathematical modelling activities based on Study and Research Paths (SRP) from the Anthropological Theory of the Didactic (ATD) including elements of lesson study. García, Higuera, and Bosch (2006), Barquero (2009) and Jessen (2014) have shown how SRP can be used for the design of modelling activities for students at all levels of the educational system. In those studies, modelling functions as a vehicle for learning mathematical content knowledge (see further in Julie & Mudaly, 2007, p. 504). This was also the purpose of the SRPs, developed by the participants of our PD. However, it has been reported that Study and Research Paths for Teacher Education, SRP-TE (Barquero et al., 2018) proved to be difficult for teachers to implement and they turned to transmission of knowledge when back in their own classrooms with designs developed in a PD. In our study, we draw on the suggestion of creating supporting structures for in-service teachers as part

of courses on SRP (Muñoz, García, & Fernández, 2018). We adopt the model suggested by Miyakawa and Winsløw (2013), called para-didactic infrastructures, to describe the use of elements of lesson study structures in our PD. These structures cover shared preparation, observation and reflection upon some teaching. Miyakawa and Winsløw (2013) use the model to describe an open lesson observed during a lesson study festival in Japan and to point out why open lesson represents an attractive element of PD for Japanese teachers. We find it interesting to study, how elements of this PD practice can be explored in other contexts. This is the objective of this paper, which address the research question: How can we employ para-didactic infrastructures in PD for upper secondary teachers in order to support teachers' implementation of SRP based teaching in their own classrooms? To answer this, we provide a short introduction to basic notions of ATD, a description of the course and an implemented SRP.

### **The theoretical framework of ATD – and its use in the course**

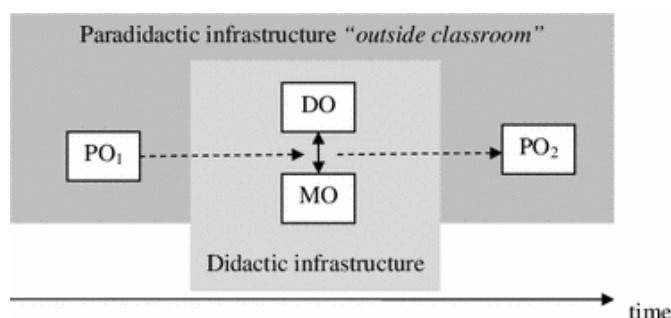

Praxeology is a core notion in ATD, where we consider it possible to describe all human activities in terms of praxeologies. A praxeology consists of two elements: praxis and logos. If we consider mathematical praxeologies, *praxis* consist of a *type of task* and the *technique(s)* to solve it. An example could be how to find the surface area of an open cylinder with radius  $r$  and length  $l$ . The technique to solve it, is the formula  $A = 2 \cdot \pi \cdot r \cdot l$ . Logos is the justification of praxis and consists of *technology* and *theory*. In the case of the cylinder, the technology is the articulation of how we can cut the cylinder open and unfold it as a rectangle. The length is then the one of the cylinder,  $l$ , and the width is the circumference of a circle with radius  $r$ . The theory is a higher level of justification, which in this case will be geometric shapes, their measures and properties. Praxeologies are connected through shared techniques, technology or theory, which form mathematical organisations (MO) from local ones sharing techniques to global ones, describing a whole domain, e.g. vector algebra (Barbé, Bosch, Espinoza, & Gascón, 2005). We can consider teachers' actions in the classroom, as the realisation of didactical praxeologies. What is observable in teaching situations, is often the techniques: the way to introduce new content knowledge, the way to pose questions, the way to organise students' work in groups etc. The didactical tasks, which the techniques answer, are addressed by the teacher when preparing the lesson. The logos of the didactical praxeologies are rarely evident, but might be based on teachers' initial education and courses on learning theory, didactics of mathematics or their teaching experiences. The latter might not count as real theory, but is still a level of justification from the perspective of the teachers. Teaching can then, be considered a set of mathematical and didactical organisations (DO) intertwined and to be realised in the classroom. Miyakawa and Winsløw presents “a theoretical approach to study mathematics teacher knowledge and the conditions for developing it in direct relation to teaching practice” based on ATD (Miyaka & Winsløw, 2013, p. 186), which is depicted in Figure 1. The model illustrates how teacher knowledge can be developed and described in terms of mathematical and didactical praxeologies, relevant for teaching a certain piece of knowledge. The didactic infrastructures refer to the interaction between the MO and DO employed. The PO's represent the paradidactic organisations. The PO<sub>1</sub> is the pre-didactic organisation, including knowledge and practices involved in teachers joined exploration and formulation of the MO to be taught and the DO required to do so. PO<sub>2</sub> is the post-didactical organisation involved in the evaluation of the realised MO and DO. In our PD, we strived

to provide teachers with situations in terms of  $PO_1$  and  $PO_2$  and to exploit those, reconsidering the knowledge to be taught, why to teach it and how to teach it – to free the teachers from habits and to construct new knowledge about teaching practices based on SRP.

SRP is a design tool suggested to design modelling activities and inquiry based teaching (García et al., 2006). The design of an SRP starts by formulating a generating

question,  $Q_0$ . Students should be able to understand, but not able to answer  $Q_0$  unless they engage in study and research processes. The study process is when students study different media: textbooks, online webpages, video materials, data from an experiment etc. to gain knowledge on a subdomain, method, formula and more. This process is considered to be the deconstruction of knowledge. In the research process, students combine knowledge acquired in the study process with their existing knowledge forming answers to derived questions (which in the end lead to a coherent answer to  $Q_0$ ). This reconstruction of knowledge is considered the result of students' interactions with the milieu (Jessen, 2017, p. 224). The dialectic between study and research is assumed to give rise to derived questions. As for the SRP described below, a derived question could be: “in order to answer how long the route is, I need to know how to find the length of a vector?”. This question addresses the content, but derived questions can also be technical in their nature, such as how to define a vector in Geogebra? In ATD we consider those questions and their answers as mathematical and instrumented praxeologies. In the planning of a SRP, it might also be relevant to consider meta-cognitive teacher questions such as “what have you done so far in order to answer  $Q_0$ ”. This would be considered part of the didactical praxeologies employed by the teachers. Providing teachers with paradidactic infrastructures, meta-cognitive questions would be addressed in the  $PO_1$ , when preparing the lesson discussing whether to pose such a question and how it would affect the students learning outcomes. This shared preparation is supposed to develop their didactical praxeologies. During the  $PO_2$ , the teachers' didactical equipment will be further developed, when discussing the learning outcomes of the students in relation to the group of teachers' choices regarding didactical techniques.

A way to share the learning potentials of an SRP, is to map the derived questions and how they are related, which form a mind map like tree-diagram. In ATD these diagrams are created by researchers based on the epistemological analysis of the domain being taught (e.g. see Jessen, 2014). In our PD, the participants were encouraged to develop these maps based on their knowledge on the students' prerequisites, knowledge to be taught, preferred textbooks, possible google hits etc. This is one way to engage the teachers in studying the MO of their teaching, which is the first challenge for teachers engaging with SRP in PD (Barquero et al., 2018). In our PD, the participants were suggested to use the tree-diagrams, named ‘knowledge-maps’, as navigation tools when teaching (see Jessen & Rasmussen, 2018). When evaluating the teaching design in  $PO_2$ , we wanted the teachers to discuss what questions and answers were raised by the students during the teaching, and based on this, discuss

**Figure 1: The sketch show the didactic and paradidactic infrastructures surrounding teaching (Miyakawa & Winsløw, 2013, p. 189)**

the learning outcomes. In ATD research, we use discourse analyses to identify what answers or part of answers students developed and, through those discuss, what questions they might answer. Students raise those implicitly or explicitly. This methodology is fully described in Jessen (2014, 2017). In the PD, the participants did not complete such an a posteriori analysis, but we discussed questions and answers raised by students, as result of the realised MO and DO, which led to suggestions for improving the SRP designs and a revision of the lesson plans. As inspiration for the DOs required to realise an SRP, the participants in our PD were presented with the DOs employed in Jessen (2014, 2017) (group work, sharing sessions, strict time schedules etc.). They were articulated as methods to realise SRPs. The participants were encouraged to develop their own methods, drawing on their teaching experiences. For each group of teachers, the planned teaching was materialised in a lesson plan similar to those developed for the MERIA project (Jessen & Winsløw, 2018, p. 3) with formulations of concrete learning goals, broader goals, age of students, time of school year, type of institution, teaching materials including  $Q_0$ , media suggested to the students and the knowledge-map showing the teachers a priori analysis. In the end, we had four columns indicating: timeline, teachers' actions, students' actions and observation notes. During the realisations, the observing group members took field notes on how the lesson differed from the plan and what questions and answers were provided by the students. Depending on, what was possible, the participants in the PD collected testimonial from the lessons in terms of: video recording of students presenting their work, pictures of students' presentations, handed in assignments etc. Inspired by Barquero et al. (2018), we describe the realisation of the PD through one group of teachers' work with a SRP on vector algebra, after providing the context of the PD.

### **The context of the PD and course design**

In 2017 upper secondary education was reformed in Denmark, where mathematics was altered with respect to suggested teaching methods and elements of content knowledge (re)introduced, where others were skipped. This created a need for a PD on didactics related to the specific changes of the content (see elaboration in Jessen & Rasmussen, 2018, p. 346). The course was designed as 7 teaching session lasting 4 hours each. The course covers: the why's and how's of inquiry based teaching and modelling based on SRP as a design tool, piecewise linear functions, vector algebra, discrete mathematics and probability theory. Participants were encouraged to join with a colleague so the teachers could collaborate between sessions, and potentially build para-didactic structures as described in Figure 1. A total of 47 teachers participated (with 1-30 years of teaching experience) from all over Denmark and formed groups of approximately 4 teachers, which they kept working with throughout the course. Every teaching session, except the first one, had an element of sharing and peer-feedback on SRP designs ( $Q_0$ , knowledge maps, media, etc.) and on the realised SRPs of each group, based on testimonial from the classroom shared with the rest of the participants. Before ending each session, all groups presented their ideas for the next SRP and got feedback on formulation, feasibility of the lesson plan and further media. The groups then improved their SRPs and lesson plans before realising them in their classrooms. Not all teachers were able to complete or test their SRPs due to extraordinary workloads implementing the reform. But most participants were eager to share and get feedback on their ideas and experiences. The knowledge collected on the PD (from the  $PO_1$  and  $PO_2$ ) is the teacher's notes (which is also the author of the paper), the finalised

lesson plans and the documentation collected and shared by the participants from their implementation of SRPs. Hence, the course does not as such create para-didactic infrastructures around the teachers' practice, but rather it offers the teachers *para-didactic situations* to initiate reflections and professional development.

### **An example of para-didactic infrastructures from the course**

In this section, we will describe an example of how the para-didactic situations were implemented in the PD. A group of teachers worked with the problem of introducing vector algebra in grade 10, which earlier was taught at grade 12. During the third session of the PD, the participants shared teaching materials on vectors. Participants compared materials with the new curriculum and discussed what elements could be captured in a generating question,  $Q_0$ . They agreed, that a problem concerning routes and navigation, could create a need for the geometric definition of a vector, which they found interesting. The  $Q_0$  should not require any knowledge from physics, since a great number of the mathematics students do not take physics. This is considered the initiation of the  $PO_1$ .

During the fourth session of the PD, the groups shared initial formulations of their  $Q_0$ 's, they orally explained possible paths or strategies for the students to take, when trying to solve the problem. Our group presented the idea of letting students imagine they were a captain in the Caribbean Sea, who needed to guide his crew from one city to another. The group had found a map and a compass rose and wanted to include Geogebra, but hesitated on how to do this: should they provide students with coordinates or let them draw gridlines on the paper version of the map in order to transfer the route to Geogebra? The choice of media depended on this decision. It was discussed in general at the PD, if students would need vectors or simply use geometry – would suggested media inspire the students to use the notion of vector? It was discussed if the word *vector* should be mentioned in the  $Q_0$  and how that would affect the students' learning. These questions are considered tasks, which might develop teachers' didactical praxeologies and a further enrich the  $PO_1$ . The group of teachers completed their SRP design and lesson plan after this session. The learning goals, stated in the lesson plan, for the 120 minutes teaching were: "to know the geometric definition of vectors including position vector, be able to construct a sailing route according to the problem in terms of vectors or linear combination of vectors (incl. being able to add vectors based on their coordinates, be able to scale up vectors), determine the length of a vector and be able to do this in Geogebra". The broader goals of the lesson were: "to gain intuition of vector addition being commutative and associative as well as gain knowledge on unit vectors, see the need for them and deduce one from any given vector". Further the group expected the students to develop problem solving competency and aid and tool competency, while working with the problem. The generating question the group formulated was as follows:

" $Q_0$ : You are a captain in the Golden Days of piracy in the Caribbean and you are to guide your ship from Havana to Santo Domingo (see the attached map). Your crew covers 'landlubbers', 'treasure hunters' and sailors. They only answer to directions formulated as: "go 20 miles south (S), then 30 miles south east (SE) and then 100 miles North West (NW)". A while ago you made the distance from Aruba to Montserrat in 3 days and you expect to travel by the same average speed. What orders would you give your crew and when do you expect to arrive?"

**Figure 2: A screen dump showing the Geogebra file and the compass rose handed out**

The students were provided with a Geogebra file where the window looks like the picture on the left side of Figure 2, where unit vectors indicating the directions of N, S, E and W were defined together with points indicating the mentioned cities. Furthermore, students were provided with a compass rose on a piece of paper as the one shown in the right side of figure 2. Media suggested to the students, but not required to use, was: 10 pages in a textbook and a short manual introducing vectors in Geogebra created by the teachers. The group expected students to find media online e.g. Wikipedia and Webmatematik, both in Danish. The lesson was planned to start by showing the students  $Q_0$  and the suggested media. Furthermore, the teacher had added a function to the Geogebra file called “vector from starting point”, forcing Geogebra not to draw all vectors from origin. From the perspective of ATD, we consider the Geogebra file the milieu of the SRP. Students were expected to explore how they can construct a route based on points, lines and vectors depending on how they adapt to the milieu, study the notion of vector and develop an answer in the Geogebra file. In this respect, students are learning from the dialectic between media and milieu, between research and study processes.

The introduction of the problem, media, the Geogebra file, the connection of computers, and dividing the class into groups of three is estimated to take 20 minutes. The students are planned to work on the problem for 20 minutes, where the teachers observe the students and assist them with technical problems in Geogebra. The students present their work during the last 20 minutes. After the lunch break the teacher spends 5 minutes reminding the class of strategies presented earlier and introduce the Geogebra function “vector from starting point”. Then the groups had another 20 minutes preparing before using 20 minutes on students’ second presentations. During the last 15 minutes the students are asked to write down their solutions and strategies with arguments, why they chose the described strategies. After the lesson the students hand in the description together with their Geogebra file. During the following lesson, vector exercises similar to those of the written examinations were worked on by the class. The lesson plan represents the group of teachers’ outcome of the  $PO_1$ .

The teachers summarised their experiences and observations and wrote it down straight after the class. Together with the observation notes taken during the lesson, they completed the lesson plan, and from this we get a picture of the initiation of the  $PO_2$ . Furthermore, the teachers video recorded the two sharing sessions, where the students connected their computers with the projector and shared their

work. During the fifth session of the PD, the teachers presented their experiences with their SRP by sharing the lesson plan, and video recordings. Based on this it was discussed, if the learning goals were achieved and how they were achieved. The videos showed that many students started working with line segments creating a need for directions corresponding to NW, SE etc. This led the students to experiment with the notion of vector and Geogebra syntax. Some students created a compass rose, defining the vector NE as starting from (0,0) and ending in (1,1) and NNE as the vector with end point  $(\frac{1}{2}, 1)$ . But the groups found it unpractical with “unit” vectors of different lengths, when calculating the length of the route. Hence, the students needed real unit vectors, which were discussed in relation to the unit circle. In the PD, participants agreed that most students had achieved the intended learning during the two hours. However, it was questioned, if all students were able to solve the tasks of the following lesson, if not being allowed to use Geogebra. What was questioned was the strength of the logos of the developed praxeologies and if those could be used in other contexts e.g. pen and paper mathematics. The peer-feedback and discussion of the realised SRP led to suggestions for improvement of the design and the lesson plan, which concluded the PO<sub>2</sub>.

## Concluding remarks

From an electronic survey evaluating the PD, we know that the participants felt obliged to prepare, to implement and share experiences because of the structure of the PD. Participants noted that it was the first time they were allowed and encouraged to dwell on and discuss students learning in this detail – and similar for the planning of teaching. This seemed to be sufficient support, making participants comfortable enough to implement their SRP designs in their classrooms. The sharing further encouraged them to realise their SRPs, because of the contagious enthusiasm from those who already tried it. The numbers of realised SRPs indicates, that creating para-didactic situations might further teachers’ outcomes of PDs in terms of implementing SRP based modelling in their practice. Still, more research is needed in this area. What is the role of the researcher, teaching the PD? How does the PD affect teaching practices in the long run? Are the collaborations between participants sustainable and under what conditions? And what research methodologies can capture the MO and DOs developed by students and participating teachers respectively in large-scale studies?

# Development of group creativity in mathematical modeling

Hye-Yun Jung<sup>1</sup> and Kyeong-Hwa Lee<sup>2</sup>

<sup>1</sup>Graduate School of Seoul National University, Korea; hy0501@snu.ac.kr

<sup>2</sup>Seoul National University, Korea; khmath@snu.ac.kr

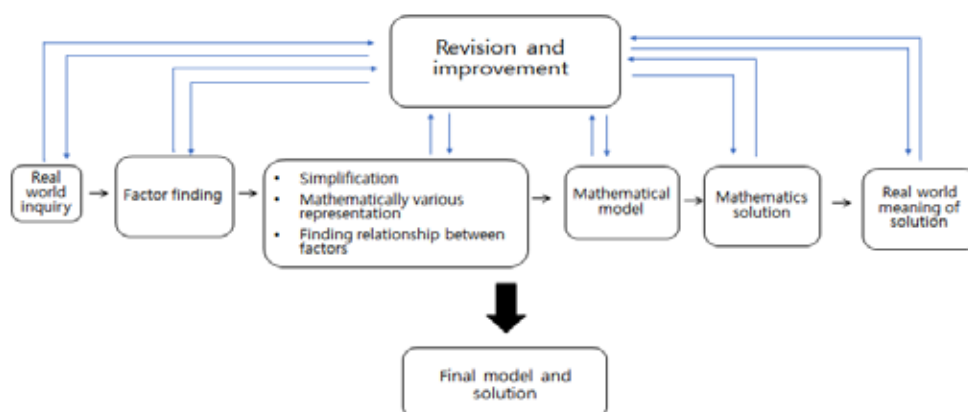

*Keywords: Mathematical modeling, group creativity, interaction, creative synergy.*

## Introduction

In many previous studies, mathematical modeling is considered an instrument to develop mathematical creativity, in rather individual contexts (e.g., Palsdottir & Sriraman, 2017, p. 49). However, there is a growing consensus that group creativity is important for the 21<sup>st</sup> century (Woodman, Sawyer, & Griffin, 1993). This study aims to explore interaction supporting the development of group creativity during mathematical modeling activities and the impact of group creativity on the mathematical modeling process.

## Theoretical Background and Methods

Mathematical modeling is a cyclic and recursive process that requires understanding a real situation and creating a model (Jung et al., 2018, p. 155). Figure 1 illustrates key stages in this iterative modeling process. Vorhölter (2017, p. 345) discuss a perspective of group based modeling activities that potentially can support the development of group creativity. Group creativity has been considered a function of individual behavior, the interaction of the individuals involved, and the creative synergy of the interaction within the group (Woodman et al., 1993, pp. 302-304). Jung and Lee (2018, p. 373) made a distinction between three types of interaction when investigating group creativity, namely: mutually complementary-, conflict based-, and metacognitive-interaction. This study aims to investigate the following two questions: (1) What types of interaction can be observed during modelling activities that support the development of group creativity? (2) What impact on the modelling process can be observed in the interactions?

**Figure 1: Mathematical modeling process chart (Jung et al., 2018, p. 155)**

Six 11<sup>th</sup> grade students and a teacher participated in this research. Based on our previous study suggesting that 3 to 4 members were appropriate, the students were divided into two groups. The researchers and the teacher worked together to design the task, and how to implement based on the

question: “What are your own strategies to prevent or cope with blackouts?”. All the lessons were videotaped, audio-recorded and transcribed. Field-notes were made during the lesson observations. Students’ worksheets were collected. The unit of analysis was the observed types of interaction at each stages of the mathematical modeling process.

## Result and Discussion

The three types of interaction supporting the development of group creativity and its creative synergy were observed in the activity and found to impact the development of their group creativity. Both mutually complementary- and conflict based-interaction were observed in both groups, but metacognitive-interaction was observed only in Group A. First, mutually complementary interaction was observed at the real world inquiry and the factor finding stages. Although each group member shared their various thoughts, meaningful information for deriving mathematical model was made by the accumulation of all those thoughts through mutual complementary interaction. The creative synergy and effect of the interaction was the expansion of factors that could affect real world phenomena related to blackouts. Second, conflict based interaction was observed at the simplification stage. Because of the diversity of thoughts and their inconsistency, conflicts had occurred among group members. This interaction resulted in rich evidence, as the creative synergy, for key factors to consider and clarification and validation of the criteria to evaluate the selected key factors. Third, metacognitive interaction was observed at the mathematical model derivation stage. Each group reflected on the modeling process and their initial mathematical model. As a result, the students could have an elaborated mathematical model with reasonable justification. In this study we extended the scope of the effectiveness of mathematical modeling to develop creativity education from the individual context to the group context. Previous studies stressed the necessity of practical studies on interaction as a process of supporting the development of group creativity (Sawyer, 2012, pp. 243–244). This study provides the first steps in this direction.

*Both empirical modelling (EM) and theoretical modelling (TM) are essential in mathematical modelling. This study explored how graduate students promoted teaching competencies for mathematical modelling by conducting EM and TM with the pendulum task. Through the analysis of modelling lessons, we found that the experiences of both EM and TM with the same material were important for the students to understand a modelling cycle and the aims and perspectives of modelling.*

*Keywords: Mathematical modelling, teacher education, empirical modelling, theoretical modelling.*

## Introduction

Educating teachers about teaching mathematical modelling is crucial, because the instruction is demanding for teachers (Blum, 2015). Several courses, programmes and materials for supporting pre-service and in-service teachers in teaching modelling have begun to be developed around the world including CERME community (e.g., Cai et al., 2014; Barquero, Carreira, & Kaiser, 2017). Various competencies are required for teaching modelling. Borromeo Ferri (2018) elaborates four competencies for teaching modelling: *Theoretical competency (incl. modelling cycles or aims and perspectives of modelling as background knowledge)*, *Task competency (incl. multiple solutions or cognitive analyses of modelling tasks)*, *Instruction competency (incl. interventions, support and feedback)*, and *Diagnostic competency (incl. recognising students' difficulties and mistakes)*. She mentions that these four competencies are the basis for the structure of teacher education on teaching modelling. Although these four competencies are related each other strongly, theoretical competency is necessary and important background for teachers' practice on teaching modelling (Borromeo Ferri, 2018).

Some of the common modelling approaches include empirical modelling, theoretical modelling and so on (Ang, 2018). Berry and Houston (1995) mention that both empirical modelling and theoretical modelling are essential in mathematical modelling. Similarly, it might be valuable for teachers to experience both modelling and understand their features in order to foster Borromeo Ferri's (2018) teaching competencies for modelling (e.g., theoretical competency). Limited research exists, however, on teacher education involving both empirical modelling and theoretical modelling. In this study, we explore how teachers promote Borromeo Ferri's (2018) teaching competencies for modelling through teacher education addressing both empirical and theoretical modelling.

## Study Background

### Empirical modelling (EM) and theoretical modelling (TM)

Berry and Houston (1995) define data-driven modelling cycle as *empirical modelling (EM)*. EM cycle includes collecting data through experimentation and measurement, making sense of data, and making graphs and regression equations that fit to the data. Berry and Houston (1995) mention that “[e]mpirical models are fairly easy to find providing that we are given or can collect the data from appropriate experiment.” (p. 10), and that “[e]mpirical modelling] has severe limitations in the validity of our interpretations from the graph.” (p. 10), and that “[t]he mathematical answer might be perfectly correct but the interpretation in the context of the real world is meaningless.” (p. 12). On the other hand, Berry and his colleague call theory-driven modelling process a *theoretical modelling (TM)*. They recognize TM process as a different one from EM process. They conceive TM process as mathematical modelling including understanding the problem, identifying the important features, making assumptions and simplifications, interpreting and validating the model, and improving the model and explaining the outcome. Both EM and TM are required to understand and describe the real world, and predict results (Berry & Houston, 1995, p. 23). This paper focuses on both EM and TM as components of mathematical modelling.

### Teacher education on empirical modelling and theoretical modelling

We reviewed how EM and TM were addressed in pre-service teacher education on modelling from the International Community of Teachers of Mathematical Modelling and Applications (ICTMA) (see table 1). We focused on six chapters mentioning the concrete teaching tasks and materials. One chapter addressed only EM task; four chapters addressed only TM tasks; one chapter addressed both EM tasks and TM tasks. None of chapters used same material throughout EM and TM. If pre-service teachers tackle both EM task and TM task, they can understand modelling in a multifaceted manner. Furthermore, they can grasp the connection between EM and TM by experiencing EM and TM using the same material.

Authors	EM Task	TM Task
Tan & Ang (2013)	Car stopping distance task	Fuel tank calibration task
Winter & Venkat (2013)		Contextual word problems
Widjaja (2013)		Parking space task
Hagena (2015)		Modelling task “Brickhouse”
Villarreal, Esteley, & Smith (2015)	Trash and recyclable collection	
Villa-Ochoa & Berrio (2015)		Planting trees problem

**Table 1: EM and TM tasks in pre-service teacher education from ICTMA-book chapters**

This study addressed the research question: *How did graduate students promote teaching competencies for modelling (e.g. understanding of modelling cycle and significance of mathematical modelling) by experiencing both EM and TM with the same material?*

## Design and Methodology

A pilot study of mathematical modelling lessons for teacher education which comprised four lessons (90 mins each) was designed and implemented for two Japanese in-service teachers and two pre-service teachers. Student A had 16-years teaching experience in lower-secondary schools, whereas student B had 20-years in upper-secondary schools. Student C and B were pre-service teachers and graduate students in mathematics education at the first level. The instructors were the first and second authors. The participants had little knowledge about modelling.

Berry and Houston (1995) illustrate two examples of EM and TM (i.e., audio cassette recorder and pendulum). We consider the pendulum example a better case for novice teachers of modelling and chose that. From the viewpoint of EM, the pendulum example is easy to image its movement, to realize important variables, and to collect data. From the viewpoint of TM, the needed knowledge of mathematics and physics for the pendulum is less than the recorder example. Hence, in the pendulum phenomenon is easy to connect EM with TM. The pendulum phenomenon sometimes induces students' misconceptions and their own ideas about matter (Osborne & Freyberg, 1985) through EM, and students' cognitive conflicts result from the misconceptions (Saeki, Ujiie, & Tsukihashi, 2001). TM, explaining the mechanism of the phenomenon, becomes inevitable activities to resolve the cognitive conflicts. The main theme of the lessons and main pendulum EM tasks and TM tasks are shown in Figure 1.

### Main Theme of the Lessons

To consider and clarify the key points for the development of teaching materials and problems that are related to the daily situation like the pendulum.

### Main Pendulum EM Tasks

Let's find the relationship between the pendulum length and period empirically.

- There is the scene of a girl rowing a huge swing in the introduction of the Japanese famous animation video. How long is the huge swing length when the swing period is twelve seconds?
- Let's confirm your conjectures of the huge swing length based on the result of the pendulum empirical experiment.

### Main Pendulum TM Tasks

Is the empirical result of the huge swing length true? Let's verify it theoretically.

- Let's find theoretical formula with the knowledge of mathematics and physics.
- Compare the regression equation elicited from EM with the formula elicited from TM.

**Figure 1: Main theme of the lessons and main pendulum EM and TM tasks**

The activities of modelling lessons for teacher education are shown in Table 2. In the first lesson, the students elicited and choose variables concerning the pendulum empirically through graphing calculators and sensor kits. In the second lesson, they drew graph using data from experiments and performed regression. In the third lesson, they conjectured and verified graphs of Displacement-Time, Velocity-Time, and Acceleration-Time about pendulum based on the physical knowledge. In addition, they elicited the formula about the proportional relationship between displacement and acceleration. In the fourth lesson, they elicited the formula  $T=2\pi\sqrt{l/g}$  and confirmed the consistency between the

theoretical model and empirical model in the first lesson. At last, they looked back on the learning processes in the lessons from the viewpoint of modelling cycle.

Sequence of Lessons	Activities in Lessons	EM	TM
1 <sup>st</sup> lesson	Eliciting variables concerning the pendulum (e.g. mass of bob, amplitude, and pendulum length) Finding that the pendulum period depends on the pendulum length through teacher's demonstration Collecting data about the pendulum length ( $l$ ) and pendulum period ( $T$ ) through graphing calculators and sensor kits		
2 <sup>nd</sup> lesson	Plotting data and draw the graph from the data Eliciting the regression equation $T=2\sqrt{l}$ Checking the equation using data from experiment Drawing hypothesis graphs of Displacement-Time, Velocity-Time, and Acceleration-Time about pendulum		
3 <sup>rd</sup> lesson	Verifying students' graphs of Displacement-Time, Velocity-Time, and Acceleration-Time about pendulum based on the physical knowledge Drawing hypothesis graphs of Displacement-Restoring force, and Displacement-Acceleration Verifying students' graphs of Displacement-Restoring force, and Displacement-Acceleration based on the physical knowledge Eliciting the formula $F = -Kx$ about the proportional relationship between restoring force and displacement based on the graphs Eliciting the formula $F = ma$ about the proportional relationship between restoring force and acceleration based on the graphs Eliciting the formula $-Kx = ma$ about the proportional relationship between displacement and acceleration		
4 <sup>th</sup> lesson	Eliciting the formula $T = 2\pi/\omega$ between pendulum period and angler velocity based on the definition of angler velocity Reformulating the relationship $F = -m\omega^2x$ between restoring force and displacement by using angler velocity and the mass of the bob Reformulating the relationship $T = 2\pi\sqrt{m/K}$ between pendulum period and the mass of the bob by using $T = 2\pi/\omega$ and $F = -Kx$ Eliciting the formula $F = -mgx/l$ about the relationships between restoring force and pendulum length by using the mass of bob, gravity and displacement Eliciting the formula $T=2\pi\sqrt{l/g}$ by using $T = 2\pi\sqrt{m/K}$ , $F = -mgx/l$ and $F = -Kx$ Confirming the consistency between the theoretical model and empirical model, the regression equation, in the first lesson Looking back on the learning processes in the lessons from the viewpoint of modelling cycle		

Note: =EM activity; = TM activity

**Table 2: Outline of modelling lessons**

Our data collection comprised students' descriptions in the post-lesson questionnaires about material development, teaching design, and teaching implementation with real-world context. Their descriptions were coded and categorised according to Borromeo Ferri's (2018) teaching

competencies for mathematical modelling. In this study, three of the four abilities were confirmed as shown in Table 3.

Competencies and focused contents	Examples of students' descriptions
<i>Theoretical competency</i>	(A) Descriptions about process and phases related to the transitions between real world and mathematical world
(A) Knowledge about modelling cycles	(B) Descriptions about the significance of modelling and modelling tasks
(B) Knowledge about goals/perspectives for modelling and modelling tasks	
<i>Instruction competency</i> (Knowledge about interventions, support and feedback)	Descriptions about the necessity of the interventions for connecting between the real world and the mathematical world
<i>Diagnostic competency</i> (Knowledge about students' difficulties and mistakes)	Descriptions about designing teaching modelling according to students' abilities

**Table 3: Students' descriptions according to Borromeo Ferri's (2018) teaching competencies for modelling**

## Results

This section illustrates the findings about students' understanding of modelling cycle, aims and perspectives of modelling, and beginning of understanding related to teaching modelling.

### Students' understanding of modelling cycle including EM and TM

Student B summarized the modelling cycle including EM and TM (Figure 2).

1. The contents of the task are interesting for students.
2. Students can experiment and analyse phenomenon in real society.
3. Students can elicit mathematical expressions like equations from the experimental results.
4. Phenomenon in real society can be translated into mathematical contents.
5. The mathematical contents can be solved with students' mathematical knowledge.
6. The mathematical results can be validated and be applied to the phenomenon in real society.
7. Students can realize the usefulness of mathematics.

**Figure 2: Student B's description to post-lesson questionnaires**

Student B clarified the modelling cycle through the modelling lessons. Description related to the modelling cycle was only one; however, whole students discussed about the modelling cycle in the reflection of the lessons. They all might understand the modelling cycle including EM and TM.

### Students' understanding of aims and perspectives of modelling and modelling tasks

Three students described aims and perspectives of modelling and modelling tasks. Student C understood the difference between EM and TM as perspectives of modelling: "Modelling with experiments was concrete for me and was pleasant to imagine the result of pendulum. But, I wondered if the result is right or not", "Modelling without experiment was difficult for me, but the process and the result of formula was right", and "The modelling with the experiment of pendulum was very interesting. The pendulum experiment deepened the understanding of the period of

pendulum”. Student A and Student B identified the usefulness of mathematics as an aim of modelling. Student A described that the lessons of modelling could convey the usefulness of mathematics to school students: “Through the lessons that connected between mathematics and the real world, students would be surprised that mathematics is hidden in real-world situations and they might be able to notice the usefulness of mathematics”. Student B described the role of mathematics in real world and society: “Mathematics is used at various places in the real world. For example, the cord, GPS, and statistics. I would like to develop the lessons emphasizing to realize that mathematics might be powerful and useful for students to solve real world problems”.

### **Beginning of understanding related to teaching modelling**

In the fourth lessons, four students reflected the learning processes from the viewpoint of modelling cycle. From these experiences, they found the importance of observing students’ situation and of preparing teaching materials for EM and TM. Students A, C, D realized the necessity of the interventions in EM and TM. Student A emphasized that teachers should grasp students’ mathematical knowledge before modelling lessons, especially TM activities: “I would like to design my lessons that the students are able to consider real world problems and to grow their viewpoint for consideration using previous mathematical knowledge. Student D described similarity as follows: “I experienced EM and TM. Through my experience, I thought that TM was difficult for students who did not get some knowledge of mathematics and physics. I think it is important to consider students’ situation and to prepare for teaching materials to diverse students”. Student C described the importance of teachers’ pre-experiment in EM: “For modelling with experiment, I must make plan to have included time for carrying preparations of experiments and means thoroughly”. Student A understood the necessity of the intervention for connecting between the real world and the mathematical world. He described as follows: “The facilitation of connecting the mathematical world and the real world is necessary”. He realized the needs of preparation for mathematical modelling. Student B found the importance of modelling lessons according to students’ abilities: “Through the lessons for modelling, I should plan the lessons flexibly and diagnose students’ situation and understanding in case of the difficult modelling with mathematics for students”.

### **Discussion and Conclusion**

This paper has addressed some aspects of students’ understanding about modelling cycle and significance of modelling through the experiences of both EM and TM with the pendulum task. From the results of the transcripts and the descriptions in the post-lesson questionnaires, three results became clear. First is students’ understanding of modelling cycle including EM and TM. Second is students’ understanding of aims and perspectives of modelling and modelling tasks. Third is beginning of understanding related to teaching modelling that included the necessity of the interventions for connecting between the real world and the mathematical world, the necessity of the facilitation in EM and TM, and designing teaching modelling according to students’ abilities.

These results demonstrated the development of Borromeo Ferri’s (2018) theoretical competency, instruction competency and diagnostic competency. For example, the first and the second results correspond to the theoretical competency. Student A’s description on the necessity of the intervention for connecting between the real world and the mathematical world and students A, D, C’s

descriptions on the necessity of the facilitation in EM and TM correspond to the instruction competency. Student B's description on designing teaching modelling according to students' abilities corresponds to the diagnostic competency. However, Niss and Højgaard (2011) point out that competences are difficult to measure and should be done in a 3D model with technical level, degree of coverage, and radius of action. This study focused on the technical level and degree coverage; hence, the in-depth assessment of competency is our future work. We believe that experiencing EM and TM with the same material (Berry & Houston, 1995) worked for the above results. The students confused the difference between the misconception (Osborne & Freyberg, 1985) and the result of experiment in EM. In fact, Student D answered this situation: "Findings from my experience of pendulum were uneasiness". This uneasiness born in EM became the driving force for TM elucidating mechanism inherent in pendulum phenomenon mathematically and physically. Through the experiences of both EM and TM using the same material, the students were able to consider real-world problems deeply connecting between inductive and deductive viewpoints. They were able to recognize that EM and TM were like opposite sides to the same coin and essential components of modelling cycle through the reflection of learning processes via a diagram of modelling cycle (Kawakami, Saeki, & Kaneko, 2018). In this study, EM produced intellectual curiosity and uneasiness and elicited inevitability of the TM. However, the previous study on teacher education on modelling did not focus on the relationships between EM and TM. We need rethink the role of experiencing both EM and TM with same material in developing teachers' teaching competencies for modelling in other cases.

# Measuring an aspect of adaptive intervention competence in mathematical modelling processes

Heiner Klock<sup>1</sup> and Hans-Stefan Siller<sup>2</sup>

*To provide appropriate support during modelling processes is challenging for teachers. Especially modelling tasks based on a holistic approach offer a multitude of solutions that the teacher has to deal with. Several authors therefore emphasize the importance of a precise diagnosis in the intervention process. Adaptive interventions are a suitable support for students whereas a previous diagnosis should be the basis. A process model is presented that describes an idealized intervention adapted to students' modelling processes. In this model, a diagnostic and an intervention-related part can be distinguished. We investigate the question whether adaptive intervention competence can be described through a one- or two-dimensional model and whether a cause and effect relationship between a correct diagnosis and the selection of an adaptive intervention can be determined. The results indicate that the meaning of a previous diagnosis can be confirmed empirically in this sample.*

*Keywords: Diagnosis, intervention, adaptive behaviour, linear regression.*

## Introduction

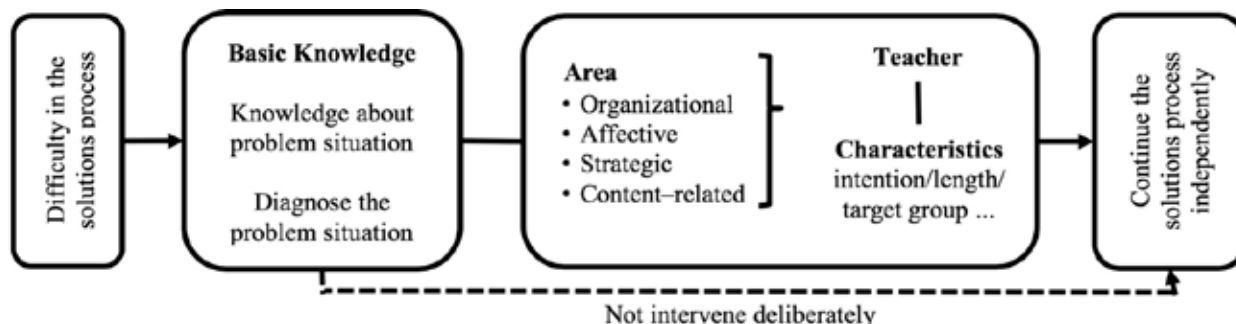

When using modelling tasks according to a holistic approach, group work is an effective instructional strategy (Clohessy & Johnson, 2017). In less structured and independently carried out working processes, adaptive teacher interventions provide appropriate help for students. When difficulties arise in group work, teacher interventions should ensure progress without giving too many content-related hints on the solution. Frequently, a spontaneous reaction is necessary and there is little time available. Adaptive interventions should create a balance between direct instruction and students' independent work (Leiss, 2010). However, intervening adaptively is therefore a challenging activity for teachers (Blum & Borromeo Ferri, 2009).

For this reason, a modelling seminar was developed and integrated into university teacher training. The overall intention is to facilitate pre-service teachers' adaptive intervention competence and evaluate their development through the seminar. By a teacher intervention, we generally mean a verbal intrusion into the students' solution process (cf. Leiss, 2007). We present the construct of adaptive intervention competence which is measured using a quantitative test instrument. In this article, the data of the seminar are used to examine the dimensionality of the construct and to investigate the cause and effect relationship between diagnostic and intervention-related aspects.

## Adaptive interventions

Leiss (2007) has developed a general model for teacher interventions (see Figure 1) in which he differentiates between three aspects: the basic knowledge, the area and the characteristics of an intervention (Tropper, Leiss, & Hänze, 2015). A diagnosis of the situation (trigger of the intervention,

previous interventions, knowledge required to solve the task, students' competence level, time available) and a diagnosis of difficulties (type of difficulty, area and cause of the difficulty, assignment in a theoretical model – here: the modelling cycle) is necessary to create a *basic knowledge* which is crucial for the selection of an adequate intervention.

**Figure 1: Process model for general teacher interventions (Leiss, 2007; translation by authors)**

The *area of intervention* describes to which aspect the intervention refers to. *Organizational interventions* concern the design of the learning environment (“Watch the time!”). *Affective interventions* influence students’ emotional aspects extrinsically (“You can do this!”). *Strategic interventions* are help on a meta-level (“What is still missing?” (Blum & Borromeo Ferri, 2009, p. 52)). *Content-related interventions* are related to concrete contents of the task (“A car consumes 7 litres per kilometre.”). The area is the central feature of an intervention (Leiss, 2007). In particular, strategic interventions are considered to have high potential to support students to overcome difficulties in the modelling process (Link, 2011; Stender & Kaiser, 2017).

Interventions can be classified by different *characteristics* like the intention of the intervention (statement, question, request), its duration and the addressee (single student, group, whole class) (Leiss, 2007). The aspects basic knowledge, area and characteristics of an intervention describe a general and idealized intervention. Based on that, Tropper et al. (2015) defined the notion of adaptive teacher interventions which

are based on a diagnosis of the situation and can be described as an independence-preserving form of support, adapted in form and content to students’ learning process, in order to enable them to overcome a (potential) barrier in the process and to continue the process as independently as possible. (2015, p. 1226)

Four essential characteristics of adaptive interventions can be identified from this and further definitions (see Leiss, 2007; Stender & Kaiser, 2017). In our work adaptive interventions:

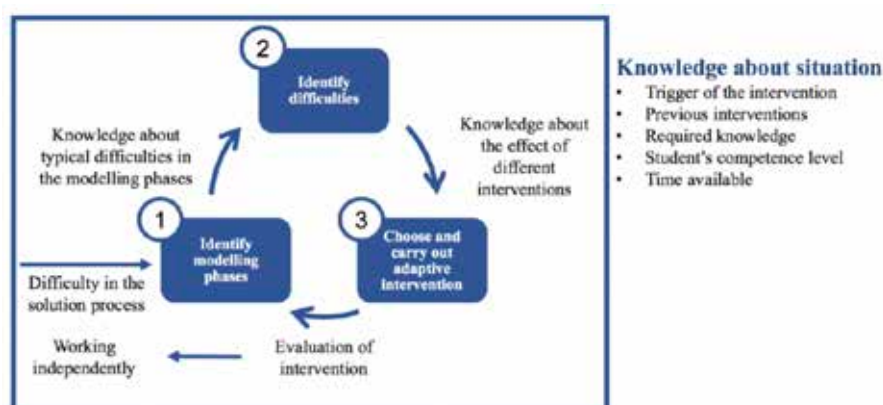

- are based on a diagnosis.
- are adapted in form and content to students’ learning process.
- provide minimal help.
- preserve independence.

These four aspects are crucial for supporting students in mathematical modelling processes. They are the basis for assessing interventions in terms of adaptivity.

## Adaptive intervention competence in mathematical modelling processes

Due to the high demands on adaptive interventions in mathematical modelling processes, a process model was developed using the work of Leiss (2007). The model describes an idealized intervention supporting groups of students *in mathematical modelling processes* (see Figure 2).

**Figure 2: Process model for adaptive interventions in mathematical modelling processes**

The Steps 1 and 2 form the diagnostic part of the model and thus the diagnostic competence. An accurate diagnosis is essential for the selection of an adaptive intervention (Blum & Borromeo Ferri, 2009; Leiss, 2007). If difficulties arise in the solution process, they have to be diagnosed. It is useful to identify the modelling phase first (Step 1 in Figure 2) in which the students are currently working (Borromeo Ferri & Blum, 2010). Based on knowledge about typical difficulties in the individual modelling phases, initial indications for the cause of the difficulty can be obtained. Several studies indicate potential difficulties in single modelling phases (e.g., Galbraith & Stillman, 2006). With the help of this knowledge a focused diagnosis is possible (Step 2 in Figure 2). Step 3 describes the choice and realization of the intervention. Few studies examined the effectiveness of various interventions. Studies by Link (2011), Stender (2016) and Vorhölter, Grünewald, Krosanke, Beutel and Meyer (2013) indicate that strategic interventions are particularly suitable. Interventions that follow rules of good communication consist of several interventions at different strategic levels (Link, 2011). However, depending on the situation and its framework conditions, organisational, affective or content-related interventions may be suitable. In Steps 1 to 3 – but especially in Step 3 – the knowledge about the situation (see Figure 2; Leiss, 2007) influences decision making. This knowledge is ideally acquired before the intervention process due to its crucial meaning for the selection of an adaptive intervention. At this point, it may be suitable not to intervene prematurely. This provides students with the opportunity to overcome the difficulty by themselves (Leiss, 2007). The adaptivity is appraised before implementation – *a priori* – on the basis of the four characteristic aspects mentioned above. Finally, an evaluation must be carried out after implementation – *a posteriori*. It has to be determined whether the intended behaviour has occurred, whether the difficulty has been overcome and whether students are working independently. The adaptivity of an intervention can finally be determined afterwards. Even if it matches all aspects of an adaptive intervention, *a priori*, it needs not be successful (Stender, 2016; Vorhölter et al., 2013), *a posteriori*. The intervention is assessed by the teacher before and after implementation. Therefore, we distinguish

between a priori and a posteriori intervention competence. If necessary, the teacher has to go through the intervention process again.

The process model describes cognitive and action-related aspects of an intervention. The ability to perform this process appropriately is what we call *adaptive intervention competence in mathematical modelling processes*.

## Hypotheses

In this article, we investigate the dimensionality of the measured construct and whether the diagnostic competence (Steps 1 and 2) and the a priori intervention competence (Step 3) show an empirical interrelation. Since various authors emphasize the importance of an accurate diagnosis for the adaptivity of an intervention (Blum & Borromeo Ferri, 2009; Leiss, 2007), our hypotheses are:

- (H1) The cognitive part of adaptive intervention competence can be described by a two-dimensional model (diagnostic and a priori intervention competence).
- (H2) There is a cause and effect relationship between diagnostic and a priori intervention competence (Klock & Siller, 2019).

## Method

Pre-service teachers were surveyed with the help of a quantitative test instrument in a pre-post-design before and after attending a teacher training seminar on mathematical modelling. We use this data to answer the mentioned research questions. Since the evaluation of the seminar is not part of this article, we refer to another publication for a description of its contents (Klock & Siller, 2019).

## Sample

The data were collected in the winter term 2017/2018 and in the summer term 2018. The pre-service teachers are all trained for teaching professions at secondary schools. The sample description is given in Table 1. The genders are distributed almost evenly, the students are on average 23 years old and are in their sixth to seventh term of study.

<i>n</i>	Gender	Age		Term	
	male/female	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
78	35/43	23.06	2.69	6.71	2.89

**Table 1: Sample description**

In order to generate a sufficient sample size for the analysis of dimensionality, the method of *virtual persons* according to Hartig and Kühnbach (2006) was applied. In this approach pre- and post-test data of the same persons ( $n=156$ ) are used in a simple logistic Rasch model. The advantage of this approach is that items' difficulty parameters are estimated using the same model in pre- and post-test. However, potential dependencies between the measured values of the same person are not considered.

## Instrument

Piloting the test in another sample ( $n=66$ ), four of ten task vignettes were eliminated based on statistical quality criteria. The test instrument (Klock & Wess, 2018; Klock, Wess, Greefrath, & Siller, 2019) consists finally of six text vignettes, each showing a modelling task and a typical students'

conversation while solving the task. The scale “diagnosis” consists of three multiple-choice items per text vignette (18 items) with four possible answers each. The scale “intervention” consists of complex multiple-choice items with four items per text vignette (24 items; see Table 2).

Scale	Number of items	Item examples
Diagnosis	6	To which phase of the solution process can the group of students mainly be assigned to? A. construct/understand .. B. simplify/structure .. C. mathematise .. D. interpret ..
	6	Diagnose students’ difficulty working on the task in this situation. The students ... A. ... have difficulties in making assumptions. .. B. ... draw the wrong conclusion from their mathematical result. .. C. ... have difficulties in understanding the context. .. D. ... use an unsuitable mathematical model. ..
	6	Please indicate which support goal you would formulate for the group following this situation. A. Independent acquisition and evaluation of information. .. B. Critical questioning of results in the modelling process. .. C. Independent construction of mental models for given problem situations. .. D. Reliable translation of simplified real situations into mathematical models. ..
Intervention	24	Please indicate which of the following interventions are suitable for an independence preserving support of modelling skills in this situation. <div style="display: flex; justify-content: flex-end; margin-right: 20px;"> <span>suitable</span> <span>unsuitable</span> </div> A. “First of all, estimates how long a car is.” .. .. B. “First, consider only part of the problem, e.g. how many cars are in traffic jams at all.” .. .. C. “Exactly, calculate this value.” .. .. D. “Think about how you could get the missing data.” .. ..

**Table 2: Item examples for the two scales “diagnosis” and “intervention” (Klock & Wess, 2018)**

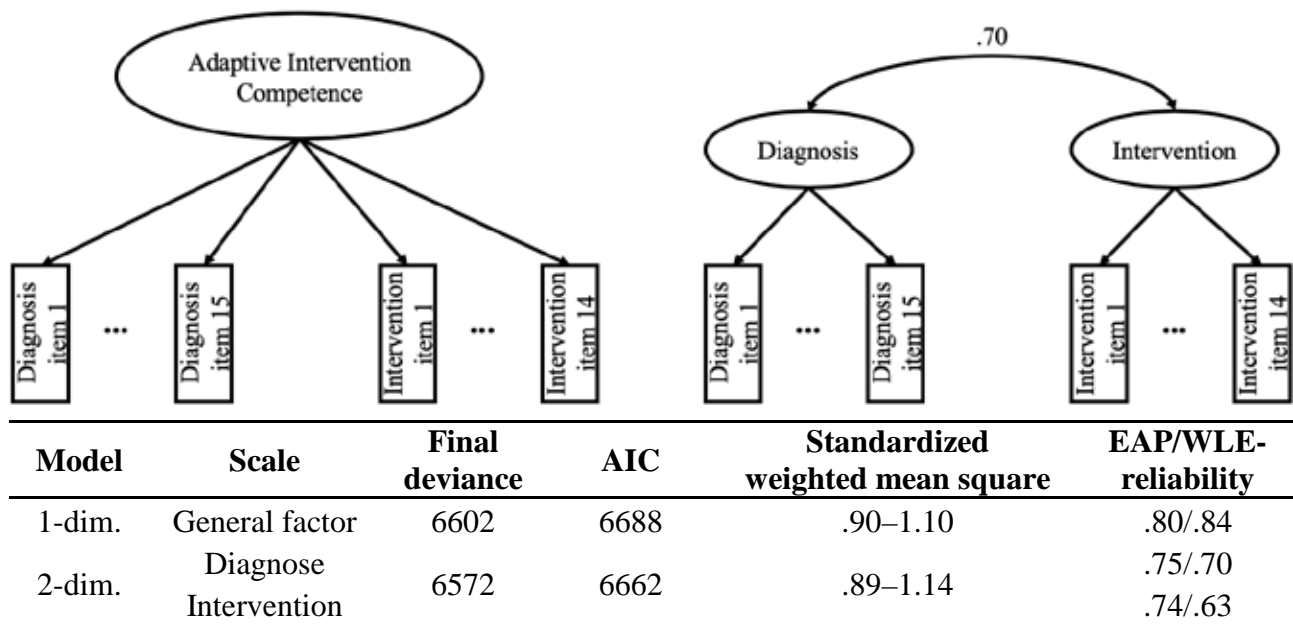

The test construction is based on the presented process model (see Figure 2). The diagnostic part is operationalized by the scale “diagnosis”. The scale measures the ability to identify the modelling phase, the difficulty in the modelling process and to select a support goal. A priori intervention competence is operationalized by the scale “intervention”. The statements have to be assessed with regard to the last three of the four aspects of adaptivity mentioned above and aspects of the situation shown by the text vignette. The items were evaluated based on expert ratings assigning scores dichotomously (0 and 1 raw points).

## Results

To evaluate the dimensionality of the construct, the simple logistic Rasch model (Rost, 1996, p. 115) was applied to compare two models (H1). The two models and the results of Rasch analysis are shown in Figure 3. The two models are compared with the help of the residual estimates (final deviance, AIC). The residuals are significantly smaller in the 2-dim. Model which indicates a better description of the data. In both models, all item-fit values are within the recommended interval (standardized weighted mean squares  $> 0.8$  and  $< 1.2$ ) by Bond and Fox (2013, p. 279), which points to a general fit of the Rasch model. The reliabilities are acceptable with regard to the EAP-reliability. All

indications point to a better fit of the two-dimensional model. We choose the 2-dim. model since it describes the data better and the reliabilities are acceptable.

The scales in the 2-dim. model correlate with high significance ( $r = .70$ ). The diagnostic and intervention-related part can thus be empirically separated but also form the construct of adaptive intervention competence in mathematical modelling processes since they are highly correlated. (H1) can be confirmed in this sample.

**Figure 3: One- (left) and two-dimensional (right) model and results of Rasch analysis**

(H2) examines the relationship between these two dimensions. For this reason, a linear regression was performed using the post-test-scores ( $n=78$ ). The weighted likelihood estimates of the Rasch model (WLE-scores) are used to calculate a linear regression between the scales “diagnosis” (independent variable) and “intervention” (dependent variable). Table 3 shows the results. The two scales “diagnosis” and “intervention” show a medium correlation ( $R = .45$ ). There is a medium goodness-of-fit for the data ( $R^2 = .20$ ) and a high test power ( $1-b_{\text{error}} = .99$ ). The variable “diagnosis” predicts statistically significant the variable “intervention” ( $F(1, 73) = 18,701, p < .001$ ). If the score of the scale “diagnosis” increases by one standard deviation, the score of the scale “intervention” increases on average by  $b = .45$  standard deviations. According to that (H2) can also be confirmed in this sample.

<i>R</i>	<i>R</i> <sup>2</sup>	Regression coefficient <i>B</i>	Standard error of <i>B</i>	95% - confidence interval of <i>B</i>	Standardized correlation coefficient <i>b</i>	Significance
.45	.20	.26	.06	[.14 ; .39]	.45	<.001

**Table 3: Results of linear regression**

## Discussion and conclusion

Within the scope of our survey, cognitive performance dispositions of adaptive intervention competence were measured. With the help of text vignettes in some extent situational abilities are

measured via the selection of a suitable but predetermined answer alternatives. The test does not operationalise the construct of adaptive intervention competence completely. Only the diagnostic and a priori intervention competence is measured. Action-related aspects are not considered in the test instrument. They can be evaluated by means of videos recorded during the seminar. The videos show pre-service teachers supporting groups of students working on a modelling task. However, it can be assumed that the cognitive skills measured are a prerequisite for an adequate diagnosis and intervention.

It was found that a cognitive aspect of adaptive intervention competence can be described by a two-dimensional model consisting of diagnostic and intervention-related parts. There is a cause and effect relationship between these dimensions. The scale “diagnosis” predicts skills measured by the scale “intervention” significantly. This can be confirmed by similar results when pre-test scores are analysed. In these data, the effect of the scale “diagnosis” is smaller than in the post-test data. Since diagnostic and intervention competences are acquired in the seminar, the significance of diagnostic skills seems to increase at higher skill levels (Klock & Siller, 2019). The diagnosis plays an important role in the intervention process. However, these preliminary results have to be confirmed by further data.

### Acknowledgment

We thank the German Ministry for Education and Research for funding the project MoSAiK (Kauertz & Siller, 2016) – support code 01JA1605 – in the framework of “Qualitätsoffensive Lehrerbildung”.

# Research into students' evaluations of given modelling solutions and their suggestions for improved modelling – Results from two empirical studies

Sebastian Kuntze<sup>1</sup> and Julian Eppler<sup>2</sup>

<sup>1,2</sup> Ludwigsburg University of Education, Germany

[kuntze@ph-ludwigsburg.de](mailto:kuntze@ph-ludwigsburg.de); [epplerjulian@stud.ph-ludwigsburg.de](mailto:epplerjulian@stud.ph-ludwigsburg.de)

*Modelling occurs not only when students solve tasks which require modelling activities – also when students evaluate given solutions of such tasks, activities which can be described by elements of the modelling cycle may be elicited. In particular, when reviewing and refining modelling solutions cooperatively in the classroom, students have to face specific requirements, such as reconstructing modelling thoughts, examining alternative modelling steps and comparing the quality of different modelling solutions. However, there is still relatively little empirical evidence related to how students deal with these specific requirements. This paper therefore focuses on empirical findings from two studies on this topic. The evidence suggests that the participating secondary students identified relevant possibilities of improving the modelling solutions, even if it was difficult for some of them to implement all suggestions in their own improved modelling solutions.*

*Keywords: Modelling, given modelling solutions, empirical study, students' suggestions for improved modelling.*

## Introduction

When implementing modelling activities in the mathematics classroom, one of the difficulties concerns the phase *after* the students' individual or group modelling work: In this phase, a dialogue about the potentially very different modelling solutions which have been produced can offer valuable learning opportunities related to broadening the students' repertoire of modelling strategies, and also related to identifying and improving non-optimal aspects of the modelling solutions. However not only for the teacher, but also for the students, this phase can be expected to be very challenging, as they have to evaluate others' solutions and to think of or even implement suggestions for improved modelling related to these solutions. Despite the importance of this phase for the mathematics classroom, empirical research on how the students deal with such challenges is still needed. The two studies reported here consequently focus on this research aim. In a corresponding instrument, secondary students were asked to comment on given modelling solutions and to give suggestions for improving the modelling thoughts shown in the given solutions. The given solutions were pre-designed in a way that offered several aspects in which the modelling could be improved. On the base of their answers, the students were further asked to actually implement the suggestions in an improved modelling attempt. The results show that a majority of the students was able to suggest appropriate improvements, but also that it was not easy for them to combine all suggestions for improvement, especially when implementing the suggestions in the solution. We conclude from the findings that specific learning material focused on given modelling solutions could be a help for the learners. We will in the following first give an outline of the theoretical background of our approach, which will

lead to the research aim of the two studies. After describing the design and methods of the two studies, we will present results, which will be discussed in a concluding section.

## **Theoretical background**

A key characteristic of tasks with substantial modelling requirements is their open-endedness, in the sense that the modelling cycle (Blomhøj & Jensen, 2003; Blum & Leiß, 2005) can be completed several times, in order to revise and improve the modelling, corresponding assumptions, and the modelling results again and again. This task characteristic can be seen at the very heart of mathematical modelling, as mathematical models very often only afford approximating exact descriptions or predictions for situations in the “rest of the world” (Blum & Leiß, 2005). As models can mostly be improved, refined in their complexity, or adjusted as far as modelling assumptions are concerned, such activities can be seen as typical for modelling. This underlines the importance of corresponding activities also for the mathematics classroom (Lesh, 2003): requirements students have to deal with when evaluating given modelling solutions or striving to improve them hence correspond to substantial learning goals when building up modelling competencies (Maaß, 2006; Blum et al., 2007; Kuntze, 2010; Brand, 2014). Evaluating given modelling solutions is hence important to study – for deepening these thoughts further, we will first introduce our understanding of tasks with substantial modelling requirements. On this base, we will then turn to key aspects of activities of evaluating given modelling solutions and identifying suggestions for improved modelling.

### **Tasks with substantial modelling requirements**

Tasks are central for the over-all instructional quality in mathematics classrooms (e.g. Jordan et al., 2006); their characteristics are key for creating cognitively activating learning opportunities. In particular, for building up modelling competencies of the students (e.g., Kuntze, 2010; see Borromeo Ferri, Greefrath, & Kaiser, 2013; Maaß, 2006) characteristics of tasks play a key role. In tasks for instance, in which the mathematical model is already given or pre-determined (e.g., Lenné, 1975), specific learning opportunities which correspond to key stages of the modelling cycle (e.g. Blomhøj & Jensen, 2003; Blum & Leiß, 2005) remain systematically unconsidered. In contrast, tasks with substantial modelling requirements emphasise activities of translating between mathematics and the “rest of the world” (see Blum, 2007; Galbraith 1995). As for such tasks there is not only one single thinkable solution, the students are offered the possibility of own decision-making, students often need to make their own modelling assumptions and to select and use mathematical knowledge which may be helpful for their modelling. (see, e.g., Maaß, 2006; Blum et al., 2007; Kuntze, 2010). The importance of task characteristics thus results from the possibilities the tasks offer to the learners with respect of modelling activities. This implies also that task characteristics can make a significant difference for the process of working on the task in the classroom. If tasks require, for instance, that explicit modelling assumptions need to be made, and if different solution approaches and results are possible, this creates the opportunity of discussing different modelling approaches with the students, of comparing these approaches, of reflecting on the assumptions and on their role for the modelling results, as well as the opportunity of reasoning about students’ evaluations of the different modelling solutions. In these activities, it makes sense to consider less the “better” or “worse” modelling results, but to focus more on reconstructing, describing, and reflecting the different modelling approaches:

such a focus promises deeper and richer learning opportunities as far as knowledge about models and modelling strategies is concerned (e.g. Lesh, 2003). The learning opportunities contained in tasks may hence have an impact on the modelling-related classroom culture (e.g., Borromeo Ferri, Greefrath, & Kaiser, 2013; Blum et al., 2007; Galbraith 1995, Lesh et al., 2010).

As space limits of this paper restrict us in discussing all relevant aspects of tasks in detail (for more detail on this topic see, e.g., Kuntze & Zöttl, 2008), we would like to shortly introduce tasks with substantial modelling requirements as tasks which are open as far as given mathematical information is concerned, which offer multiple individual solution possibilities, which relate to life contexts and corresponding material (e.g., Galbraith, 1995), which require translation processes between mathematics and the rest of the world (see Blum, 2007), which require multi-step solution processes (see results related to modelling processes in Borromeo Ferri, 2006), which encourage and enable learners to connect situation contexts with available mathematical models and to use meta-knowledge about modelling and about elements of the modelling process (see Blum & Leiß, 2005; Blomhøj & Jensen, 2003).

### **Evaluating given modelling solutions and identifying suggestions for improved modelling**

It follows from the considerations above that tasks with substantial modelling requirements will mostly lead to a variety of different solutions in the classroom, e.g. if students work in small groups on these tasks. Reviewing and reflecting on these different solutions constitutes a rich learning opportunity, as students may learn to evaluate solutions in a criteria-based way and enlarge their reservoir of modelling strategies (e.g., Lesh, 2003). When reviewing given modelling solutions that have been produced by other students, full modelling cycles can be carried out, even if the emphasis is less on producing a modelling solution and more on understanding the mathematical model and the underlying assumptions, as well as evaluating the relevance of the modelling results for the situation in the rest of the world. It is almost evident that the focus of these activities differs from a task in which a modelling solution has to be produced – but still, reviewing, reflecting on and improving given modelling solutions is highly relevant for modelling competencies.

As evaluating given modelling solutions requires multi-step thinking, such tasks can be expected to be complex for students. This highlights the importance of empirical research which focuses on students' difficulties and competencies in evaluating and improving given modelling solutions, in particular non-optimal modelling solutions. Related questions for research are the following, for instance: Are students able to make sense of given modelling solutions? What may make it more difficult or what may facilitate students' understanding of such modelling solutions? Are students able to identify non-optimal assumptions or aspects of the model? What suggestions for improved modelling can be expected from secondary students? Are the students able to really implement their suggestions in an improved modelling solution? What role can learning environments play in which the comparison between different modelling solutions is explicitly encouraged?

In this research area, the two exploratory studies presented here aim to provide insight. In the following section, we introduce our specific research aim.

## Research aim

In line with the research need outlined above, the two studies presented here aim to cast light on the question “*Can students develop suggestions for improving given examples of modelling solutions and to what extent are they able to implement these suggestions for improvement in revised modelling attempts?*” For finding out about this mainly exploratory question, an instrument was designed in which students were asked to evaluate non-optimal modelling solutions by fictitious students for three tasks with substantial modelling requirements. In Study A, one given modelling solution was given for each task. In Study B, two different solutions for each task were presented to the students. An additional exploratory research aim combining the two studies was consequently: *May a specific stimulus to the students to consider different modelling solutions encourage them in developing suggestions for improvement of the modelling solutions?*

## Design and methods

The instruments used in Studies A and B consisted of tasks, given modelling solutions and questions the students had to answer. Figure 1 shows a part of the instrument of Study B with the so-called car park task, with two given modelling solutions and with questions to the students. Study A used the car park task as well, but with only one given modelling solution, which was relatively similar to the first solution in Figure 1 (“Nicole”). From Study A to Study B, the instrument was varied systematically in the sense that study A presented only one given modelling solution per task, whereas the possibility of comparing two given modelling solutions per task in Study B might encourage the participants to reflect on different modelling approaches and corresponding modelling assumptions. The answers to the open format questions (cf. Figure 1) from the students were coded according to a top-down coding scheme, with acceptable inter-rater reliability (Cohen’s kappa amounted to 0.87 in Study B). It was coded which expected suggestions for improvement were given by the students, and whether and how the students implemented these suggestions in their own improved modelling solutions. As examples, the codes “doors” and “access pathway” will be shortly explained below at the beginning of the results section.

Both in Study A and B, the instrument was divided in three sections of 45 minutes, so that the students could work on the questions in three separate lessons. For example, the students worked on the instrument section represented in Figure 1 for 45 minutes during the first lesson. The second author and the usual teacher were present, but their role was rather passive, and clarification questions from the students were rare.

The sample of Study A consisted of 21 year 6 students (12 girls, 9 boys, aged 12 or 13 years) at a South German technical track secondary school, who worked on all three sections of the instrument. 19 of these students worked on the instrument section shown in Figure 1, as two students were absent on this school day. The participants of Study B were 17 year 7 students (7 girls, 10 boys, aged 12 or 13 years) at another technical track secondary school, all 17 worked on the instrument section shown in Figure 1. Due to space limitations, we will in the following concentrate on the students’ answers to the instrument section associated with the car park task (see Figure 1).

In class 7a, the students had to work on the following task:

Task: Car park

A new car park will be built on the grassland shown here.

How can you find out how many cars can be parked on this car park?

Solution by Nicole:

Das Auto ist 4m lang, also ist die Wiese 12m breit und 20m lang.  
 Fläche der Wiese:  $12m \cdot 20m = 240m^2$   
 Fläche Auto:  $2m \cdot 4m = 8m^2$   
 Anzahl Autos:  $240m^2 : 8m^2 = 30$   
 Es passen 30 Autos auf den neuen Parkplatz.

The car is 4 m long, so the grassland is 12 m wide and 20 m long.

Area of the grassland:  $12m \times 20m = 240m^2$

Area car:  $2m \times 4m = 8m^2$

Number cars:  $240m^2 / 8m^2 = 30$

30 cars fit on the new car park.

Explain in your own words how Nicole has thought and what she has calculated.

[Space for answer]

What else should Nicole take into account? What could she improve in her solution?

[Space for answer]

Solution by Sally:

Ich schätze die Wiese ist 50m lang und 20m breit.  
 Fläche der Wiese:  $50m \cdot 20m = 1000m^2$   
 Der Supermarktparkplatz bei mir im Ort ist 15m breit und 20m lang. Er hat eine Fläche von  $300m^2$ .  
 Er hat 18 Stellplätze zum Parken.  
 $1000m^2 : 300m^2 = 3,3$   
 $3,3 \cdot 18 = 59,4$   
 Auf dem Parkplatz finden 60 Autos Platz.

I estimate the grassland is 50 m long and 20 m wide.

Area of the grassland:  $50m \times 20m = 1000m^2$

The supermarket car park in my town is 15 m wide and 20 m long. Its area is  $300m^2$ .  
 It has 18 parking positions.

$1000m^2 / 300m^2 = 3,3$

$3,3 \times 18 = 59,4$

On the car park, there is space for 60 cars.

Explain in your own words how Sally has thought and what she has calculated.

[Space for answer]

What else should Sally take into account? What could she improve in her solution?

[Space for answer]

What do YOU think how many cars can be parked on the car park? Write down your thoughts and a calculation.

[Space for answer]

**Figure 1: Example of task, given modelling solutions (translated), and questions to students**

## Results

In *Study A*, 19 students worked on the instrument section around the car park task. In their answers, we identified 24 suggestions for improvement, all students taken together. There were two categories for suggestions of improvement of the modelling solutions, namely the category “area per

car”/“doors” (i.e. there needs to be space for opening the cars’ doors, so the assumed area per car is too low) and the category “access pathway” (i.e. the cars need an access pathway to reach the parking positions). We observed that all suggestions by the students were expressed using terms of the context (e.g. “there needs to be space between the cars”), four answers additionally used expressions related to the mathematical model (e.g. “You have to do  $50:2$ , because between the cars there needs to be space in order to open the car doors”). Among the 19 students, 10 students mentioned one suggestion, 7 students mentioned two suggestions, and 2 students did not mention any suggestion for improving the given modelling solution.

Figure 2 shows results related to the implementation of the suggestions for improvement in the students’ own modelling solutions. The data shows that out of the 10 students who made one suggestion for improvement, 7 successfully implemented this suggestion in their own improved modelling, with 1 of these students lacking of an adequate interpretation of the improved mathematical solution.

Study A: Implementation of the suggestions for improvement	Making modelling assumptions	Generating improved mathematical model	Finding improved solution according to model	Interpreting solution adequately
One suggestion for improvement ( $N_1=10$ )				
“doors” ( $N_{1a}=4$ )	3	3	3	3
“access pathway” ( $N_{1b}=6$ )	4	4	4	3
Two suggestions for improvement ( $N_2=7$ ) (“doors” and “access pathway”)	6	4	4	4

**Figure 2: Code frequencies related to the implementation of suggestions for improved modelling**

In *Study B*, there were two given modelling solutions, which meant that there were more possibilities for making suggestions for improvement. Figure 3 presents the numbers of students with certain numbers of suggestions. The data shows a range from (two) students who could not make any suggestion for improvement at all to a student who made four suggestions related to Nicole’s solution and four suggestions related to Sally’s solution (in this case corresponding to the same four codes). The codes for the suggestions relate to the area per car, the space needed for the tree, the measures assumed for the car, the inclusion of the access pathway in the model, possibilities of improving the sketch, the estimation of the size of the car park, and further suggestions.

Figure 4 displays the results related to the implementation of the suggestions in improved modelling attempts. The Figure shows clusters of cases of students: There are two students who have not improved the modelling and not made any suggestions, there are eight students who have not been successful in implementing all of their suggestions, there is a further cluster with students who succeeded in implementing all of their suggestions and two students who have implemented even more improvements than they had initially suggested. As the data of Study B was more complex than the data of Study A with only one given modelling solution, Figure 4 summarizes the elements of the modelling cycle which have been displayed individually in Figure 2 in such a way that the answers had to show that the suggestion for improvement were implemented in a complete modelling cycle.

**Figure 3: Frequencies of suggestions to Nicole's and Sally's solutions (Study B)**

**Figure 4: Suggestions and actually implemented suggestions in improved modelling (Study B)**

## Discussion and conclusions

The key aim of the study was to explore to what extent students can develop suggestions for improving given examples of modelling solutions and to what extent are they able to implement these suggestions for improvement. The findings of both studies suggest that a majority of the students was able to identify suggestions for improving the given modelling solutions. Moreover, many of the suggestions could be implemented by the students in their improved modelling solutions. However, there are also students who fail in developing suggestions for improvement. These students might either have had difficulties in understanding the given modelling solutions and/or it might have been difficult for them to consider possible alternatives to the given modelling solution. For follow-up research, it would not only be interesting to enlarge the data base and to further explore these students' difficulties, but also to compare all students' proficiency related to developing own modelling solutions with their proficiency in evaluating and improving given modelling solutions.

A further focus concerns the support of students' implementation of their suggestions for improved modelling. In the mathematics classroom, specific learning environments and learning material should concentrate on supporting corresponding modelling competencies of the students.

Considering study A and B together, the question whether only one or multiple modelling solutions should be offered to students in order to encourage their evaluation and the development of suggestions for improved modelling, the results rather do not provide a simple picture: For deciding on how many given modelling solutions should be provided in the everyday classroom, also the learners' individual competencies may be an important factor and should be taken into account.

# Effective factors of a teacher training concerning the implementation of interdisciplinary STEM-modelling projects

Jean-Marie Lantau<sup>1</sup> and Martin Bracke<sup>1</sup>

<sup>1</sup>Technische Universität Kaiserslautern, Germany; {lantau} or {bracke}@mathematik.uni-kl.de

*The modelling of the functional principle of a Segway requires an understanding of physical, technical and mathematical concepts, which are usually taught at university level. Nevertheless, the focus of two two-day-teacher trainings lied in the preparation of 11 teachers and 3 teacher students, such that they can implement interdisciplinary STEM-modelling projects with their students of Grade 10 to 12. Since 5 school projects were implemented by 7 teachers and 3 teacher students during summer 2018 we focus on the detection of effective factors and obstacles of the teacher training, concerning the implementation of the modelling projects. This paper describes the design of a one-year-study, especially the concept of the two-day teacher training and the resulting school projects. We also present first results of a qualitative study focusing on the effective factors of the teacher training based on guided interviews, which were conducted with all participants.*

**Keywords:** Teacher training, STEM-modelling projects, interview study.

## Introduction

The question of a pilot school project (Lantau, 2016) with 12 students of Grade 12 was if a STEM-modelling project concerning the functional principle of a Segway can be implemented at school. The comprehension of the functional principle of a Segway requires knowledge about modelling a Segway as an inverted pendulum to detect physical forces and energies leading to a mathematical model of a linear state space system. This system is controllable and therefore stabilizable by feedback- or PID-control which can be implemented practically to control a Lego Mindstorms<sup>®</sup> Segway (Lantau, 2017). The students in the pilot project learned many mathematical and physical concepts, mostly at university level, which are used in practice to control a Segway. Furthermore, we received the feedback of the supervising teachers that this kind of STEM-modelling-project shows their students the important role of mathematics in real-life-problems, *but* that they are not able to supervise such a STEM-modelling project on their own. This observation lead to the research question of a PhD-project, of how teachers have to be trained such that they are able to supervise this kind of STEM-modelling project on their own or in a teacher team. By this mean, in 2017 two two-day teacher trainings were offered for 9 teachers. The teacher trainings content was designed to follow the modelling cycle of Blum and Leiss (2007) and will be described in the section teacher training. Based on the teacher training, four school projects were implemented with students of Grade 12 (Lantau, 2017). Three of four school projects concentrated on the comprehension of the functional principle of a Segway, so the students learned how to use the PD-control theoretically and practically to counteract tangential forces to stabilize a Segway. The essence of the first year's PhD-project was that the design of the teacher training was successful in a way that teachers are able to supervise STEM-modelling projects with their students. Therefore, we focus on the analysis of effective factors and obstacles of the teacher training concerning the implementation of STEM-modelling projects at school with students of Grade 10 to 12 by teachers and teacher students.

## Research focus

In recent years some projects and research studies concentrated on the professional development of teachers concerning the teaching of mathematical modelling in regular lessons. In their work, Blum and Borromeo-Ferri (2011) stresses that teachers need to be aware of an optimal balance between the maximal independence of the students and the minimal help of teachers. In addition, the results of the LEMA project show that a professional development course has a positive effect on self-efficacy and on pedagogical content knowledge of teachers (Maaß & Gurlitt, 2011). Gastón and Lawrence (2015, p. 9) investigated in their work that “the research does not reveal one perfect method or set of techniques that can prepare each individual teacher to effectively teach mathematical modelling as a transferable process”. Nevertheless, most of the professional development courses for mathematical modelling concentrate on teaching teachers to use mathematical modelling processes in regular lessons or small tasks. For despite, the long tradition of mathematical modelling in Kaiserslautern focuses on interdisciplinary and real-life STEM-problems which students usually investigate in project-based learning environments such as modelling days and weeks (Bock & Bracke, 2015) it was not clear how a teacher training has to be designed such that teachers are able to supervise interdisciplinary STEM-modelling projects. Since one first approach of a teacher training concerning the mathematical modelling of a Segway seemed to be successful (Lantau, 2017), the research focus was set on the detection of effective factors and obstacles of the teacher training. In our work we refer to the model of Lipowsky, in which he describes factors and constraints to explain the effectiveness of teacher training courses (Lipowsky, 2010). Quite similar to Lipowsky’s model, Wilson (2013) and Desimone et al. (2002) investigated 5 core features for professional developments, namely the content focus, an active learning process, a collective participation, coherence and a significant duration of the teacher training.

Nevertheless, since it exists only few research results concerning teacher trainings for interdisciplinary STEM-modelling projects our research question is to explore the effective factors of the teacher training such that interdisciplinary STEM-modelling projects can be implemented at school. We want to answer our question by the help of a qualitative study in which we used guided interviews based on Lipowsky’s model. At first, the participants were asked to reflect their meaning and experiences towards STEM- modelling projects and later the interview focuses on effective factors of the teacher training which encourages teachers to implement this STEM-modelling-project. Furthermore, teachers were asked to describe obstacles during the teacher training. The participants (11 teachers and 3 teacher students) of the teacher training were interviewed after the training and those who implemented their modelling project as a result of the teacher training in summer 2018 (7 teachers and 3 teacher students) were interviewed again after their projects to detect successful factors after the transfer process of the teacher training. The interviews will be analyzed by the method of content-structured analysis (Kuckartz, 2018). Figure 1 shows the design of the one-year-project.

**Figure 1: The study design**

## Teacher training

The teacher training followed the intention that teachers learn the modelling process concerning the understanding of the functional principle of a Segway actively. Therefore, the training started by an experimental phase in which the teachers got the opportunity to drive with a Ninebot Mini Street to get aware of a Segway's functional principle. After the teachers made their driving experiences, the control process of a Ninebot Mini Street and a Lego Mindstorms<sup>®</sup> Segway were compared. Based on their own experiences and observations of the control process, the teachers set up a model for the functional principle of the Segway. During this phase, the teacher recognized that they are in their students' role while modelling a Segway, so they reflected what kind of modelling approaches can students have when they model the functional principle of a Segway. In a following phase the teachers considered possible questions which they can implement with their students concerning the context Segway. For example, such a question could be the exploration of a shortest and fastest driving of a Segway in a given course. Further contexts are to investigate the effect of the center of mass' location for the control process or to calculate an optimal route for a Segway tourist tour. The collection of possible project ideas gave the teachers the opportunity to think about possible interdisciplinary modelling projects for their students. After further project ideas were collected, the focus of the teacher training was set on the control principle of a Segway, which is described in Figure 2.

**Figure 2: The design of the teacher training**

Figure 2 shows that the design of the teacher training followed the modelling cycle of Blum and Leiss (2007), in which each step is connected to a module, which has either a physical, technical, or mathematical focus. By this design, a bilateral learning approach was offered: First, teachers experienced an interdisciplinary STEM-modelling process on their own (active learning) and secondly, they reflected on each module, whether it can be transferred into their school projects,

based on the knowledge of their students (coherence). The different modules are described in the following.

### Physics module: Situation and real model

A first model for the control process of a Segway is set up by an inverted pendulum, which contains two mass-centers, one for the wheel axis  $M$  and one for the center of mass of the Segway  $m$ . The mass centers are connected with a massless pole of length  $l$ . The aim of the control principle is to counteract acting tangential forces by a motor force  $u$  of the Segway. One can describe the inverted pendulum by two approaches. Once, by analysing acting tangential forces, leading to a nonlinear, inhomogeneous ordinary differential equation of second order:  $mg \sin \varphi - m\ell \ddot{\varphi} = u$

The second approach is done by describing the movement of the inverted pendulum by the *Euler-Lagrange-formalism* (Goldstein, 1980) in which the Lagrange function (difference of kinetic and potential energy) for the generalized coordinates *position*  $x$  and *angle*  $j$  is set up:

$$\mathcal{L} = \frac{1}{2}(M + m)\dot{x}^2 + \frac{1}{2}m\dot{\varphi}^2\ell^2 + m\ell \cos(\varphi)\dot{x}\dot{\varphi} - mg\ell \cos(\varphi) + ux$$

In a second step the *Euler-Lagrange equation* is calculated for both generalized coordinates:

$$\frac{d}{dt} \frac{\delta \mathcal{L}}{\delta \dot{\varphi}} - \frac{\delta \mathcal{L}}{\delta \varphi} = 0 \wedge \frac{d}{dt} \frac{\delta \mathcal{L}}{\delta \dot{x}} - \frac{\delta \mathcal{L}}{\delta x} = 0$$

This process leads to two equations, one describing horizontal forces and the other describing tangential forces of an inverted pendulum:

$$0 = (M + m)\ddot{x} + m\ell \ddot{\varphi} \cos(\varphi) - m\ell \dot{\varphi}^2 \sin(\varphi) - u \wedge 0 = m\ell^2 \ddot{\varphi} + m\ell \cos(\varphi)\ddot{x} - mg\ell \sin(\varphi)$$

### Mathematics module: Mathematical model and results

A mathematical model for the inverted pendulum is generated of the physical model by applying Taylor-series-approximations of first order around  $\mathbf{x}^T = (x \ \dot{x} \ \varphi \ \dot{\varphi})^T = (0 \ 0 \ 0 \ 0)^T$

which leads to the linear state space system  $\dot{\mathbf{x}} = A \cdot \mathbf{x} + b \cdot u$

$$\dot{\mathbf{x}} = \begin{pmatrix} \dot{x} \\ \ddot{x} \\ \dot{\varphi} \\ \ddot{\varphi} \end{pmatrix} = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & \frac{-mg}{M} & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & \frac{g \cdot (M+m)}{M \cdot \ell} & 0 \end{pmatrix} \cdot \begin{pmatrix} x \\ \dot{x} \\ \varphi \\ \dot{\varphi} \end{pmatrix} + \begin{pmatrix} 0 \\ \frac{1}{M} \\ 0 \\ \frac{-1}{M \cdot \ell} \end{pmatrix} \cdot u$$

In order to stabilize the linear state space system a first control technique, the PID-control (Sontag, 1998) can be applied, in which the motor force  $u$  is chosen as a weighted sum of the generalized coordinates (proportional control), its time-integral (integral control) and its time-derivative (derivative control). The parameters for the P-, I-, D-control part are usually determined experimentally regarding some conditions that have to be fulfilled to generate asymptotic stable solutions for the linearized system. Based on the *PD-control approach*, one can analytically solve a linear differential equation of second order to elaborate constraints for the control parameters  $k_P$  and  $k_D$  in order to stabilize the Segway. Furthermore, an explicit Euler-method visualizes the control process of a Segway, which was implemented in GeoGebra.

### Technics module: Real results and situation model

Even though the implementation of a simulation in GeoGebra is some kind of a technical product, a more ambitious technical approach is to combine the theoretical results with a practical control of a Lego Mindstorms<sup>®</sup> Segway. This can either be done by using preconceived Lego Mindstorms<sup>®</sup> robots and balancing programs (Valk, 2014), or by developing a practical control in Lego Mindstorms<sup>®</sup>

## School projects

As a result of the two-day teacher training 5 school projects took place in summer 2018. The structure and content focus of each project was different based on the learning group, the supervision and the time framework of the project days. The following table summarizes the school projects briefly:

<i>School and time framework</i>	<i>Participating students</i>	<i>Supervisors</i>	<i>Content focus</i>
2 days at a grammar school in Bolanden	24 students (4 female, 20 male) of Grade 10 and 11	1 teacher and 1 teacher student, as well as the teacher trainer	a) PD-control b) Functional principle of a gyroscope c) Video analysis of Segway movements
2 days at a vocational school in Wissen	16 students (7 female and 9 male) of Grade 12	2 teachers and the teacher trainer	Video analysis of a fastest Segway tour through a given course
3 days in a grammar school in Mainz	17 female students of Grade 12	1 teacher, 1 colleague and the teacher trainer	a) PD-control b) Taylor-approximations c) “Modern curve sketching” by using video analysis of Segway movements d) Shortest paths for Segway tourist tours in Mainz
3 days in a vocational school in Kusel	18 students (2 female and 16 male) of Grade 12 and 13	1 teacher, 1 colleague and the teacher trainer	a) PD-control b) Explicit-Euler-method in GeoGebra c) Control of a Lego Mindstorms-Segway
3 days in a grammar school in Daun	13 students (5 female and 8 male) of Grade 12	2 teachers, 2 teacher students, 1 colleague and the teacher trainer	a) PD-control b) Explicit-Euler-method in GeoGebra c) Euler-Lagrange-formalism

**Table 1: The resulting 5 school projects**

## Preliminary results

In our point of view, considering the brief exposition of the resulting school projects, one can assess the design of the teacher training successful concerning the implementation of *different* interdisciplinary STEM-modelling projects by teachers and teacher students. The focus of research is set on the investigation of effective factors and obstacles of the teacher training (i), as well as of the school projects (ii), such that this quite ambitious modelling project can be implemented at school. Therefore, the participants were interviewed individually after the teacher training and after their school projects. The process of content-structuring qualitative content analysis has started by analyzing all interviews along the main categories of effective factors, obstacles and assessment of the teacher training and school projects, as well as along school dependent factors, or the meaning and experience towards modelling projects by teachers in their daily life work. In this section we will give an insight into preliminary results, mainly considering effective factors and obstacles.

### Effective factors

The analysis of effective factors was done by analyzing once theoretical core features of professional development like the content focus of the training, the active learning during the teacher training, the coherence, and the collective participation (Desimone et al., 2002; Lipowsky, 2010; Wilson, 2013) and secondly indicate effective factors inductively by elaborating sub categories during the analysis of the interviews. The first results hint that most of the teachers who wanted to implement a STEM-modelling project with their students reported that it is very helpful for them that they know that the teacher trainer will support them during the project days. By this fact they know that they can ask the teacher trainer for support if they feel unsure in supervising the project. Furthermore, the teachers indicated that the mathematical and physical background of the STEM-modelling project is very profound, so that their students get an insight where mathematical concepts are used in real-life situations (content focus). On the other hand, based on the teacher training, they feel sure when elaborating the physical and mathematical concepts with their students (active learning). Some of the teachers reported that they had a lot of fun during the teacher training to learn mathematical and physical concepts of university level (content focus). Beside the theoretical background of the functional principle of a Segway, many teachers reported that the simulation of the functional principle in GeoGebra is very useful for their students, so that they get a better understanding of the mathematical background, when they can compare their theoretical results with a simulation (coherence). The most important factor concerning the implementation of a STEM-modelling project however is, that teachers have seen a concrete project concept for an authentic real-life context, which can be described by mathematical concepts, which their students are able to learn with their knowledge (content focus). Finally, teachers indicate that it was very helpful for them to explore a specific modelling project, which can be implemented at school (content focus).

### Obstacles

Since the implementation of this STEM-modelling projects requires a profound mathematical, physical and technical knowledge, most of the teacher reported that this project is very ambitious and complex to implement with students of Grade 10 to 12. As the description of the physical and

mathematical modules show, it does not surprise that teachers indicate that the advanced level of the project is an obstacle for them and their students. Furthermore, some teachers indicated that they don't have any experience concerning the work with Lego Mindstorms<sup>0</sup>. Since the teacher training was designed with phases in which the teacher could work on their own ideas, they got an insight in technical and theoretical obstacles during the working phase. In addition to that fact, almost every teacher reflected that it is quite hard to prepare the modelling project, since the possible questions, that students might ask themselves in the project can't be foreseen.

## Discussion and Outlook

The short description of the school projects and the section of the preliminary results point out that interdisciplinary STEM-modelling-projects can be implemented by teachers after a respective training. Although the analysis process of the interviews by the method of qualitative content analysis has not been finished yet, there are some hints that some of the theoretical effective factors for professional development, namely content focus, active learning, collective participation and coherence (Desimone et al., 2002; Lipowsky, 2010; Wilson, 2013), were also effective factors for the implementation of interdisciplinary STEM-modelling-projects. The first results of the analysis show that main effective factors for the implementation of interdisciplinary STEM-modelling-projects are the collective participation at the teacher training and the following collaborative supervision (i), the possibility of implementing different projects based on the context Segway (ii), the exposition of a concrete modelling-project (iii), the motivating product of a Segway (iv) and the support of the teacher trainer during the school projects (v). Furthermore, the teachers indicated that the teacher training was a necessary condition for the implementation of their school projects. The participants of the teacher training reported the deep mathematical and physical knowledge, which is necessary to supervise the project (i) as the main obstacle. The main obstacles during their implementations were the supervision of open-structured project lessons (ii) and a non-fitting learning group for the interdisciplinary school project (iii). Besides the first analysis of effective factors and obstacles of the teacher training, one main open question still is how to support teachers such that they are confident enough to implement STEM-modelling projects on their own. In order to answer this question, we asked teachers during the interviews to report us necessary conditions to implement further STEM-modelling projects in future. Fortunately, almost every teacher who successfully implemented their project reported that he or she has the principle intention to implement further STEM-modelling projects in future. First hints for necessary conditions for the implementation of further STEM-modelling projects are the collective support of colleagues during the project days and the external support, for example by offering specific teacher trainings, or the external support during the project days. Finally, it has to be stressed that the focus of this work is not on the implementation of modelling activities in *regular lessons*, since from our experience this complex and interdisciplinary STEM-modelling project is recommended to be implemented in project days.

# Instrumental genesis and heuristic strategies as frameworks to geometric modeling in connecting physical and digital environments

Diego Lieban<sup>1</sup> and Zsolt Lavicza<sup>2</sup>

<sup>2</sup>Johannes Kepler University, Linz, Austria; [lavicza@gmail.com](mailto:lavicza@gmail.com)

*This study aims to offer frameworks for exploring geometric modeling while combining physical and digital resources in teaching and learning of mathematics. Originally designed as a task to tackle pre-service teachers' learning transition from 2D to 3D under the lens of instrumental genesis approach, our study revealed how heuristic strategies from Polya spontaneously emerged through the process of digital representations. The use of physical simulation was helpful in supporting participants to better comprehend and describe action of joints and to (re)interpret their mathematical behaviour, which was not possible when they were working only in the digital environment. The combined use of both physical and digital resources appears to bring a relevant contribution for refining students' thinking and enhance their mental schemes or strategies through of the modeling processes.*

*Keywords: Geometric modeling, teacher training, GeoGebra.*

## Introduction

In this work, pre-service teachers, students in a teacher training program, were assigned to represent the kinetic simulations based on real objects' movements through physical and digital resources. Geometric modeling of seesaws using GeoGebra was analysed with a special focus on the use of perpendicular lines, symmetry features and circular movements. This was mainly related to handling geometric concepts while transitioning between both 2D and 3D representations. The aim of observing the process, including integrated and multiple representations, was to identify the benefits coming from either physical and digital prototypes and how they can support one another. Such experience fed us with some elements to our posed research question:

*In a geometric modeling approach, how can the combined use of physical and digital resources to represent joints and their movements support the 3D geometric knowledge of prospective teachers?*

Following our research approach, we observed that on the one hand, the modeling task as such played a crucial role together with the software and enhanced participants' geometric understanding; prospective teachers' behaviour could be examined and understood through the Instrumental Genesis theory (Bussi & Mariotti, 2008). On the other hand, procedures adopted by participants were aligned with Heuristic Strategies proposed by Polya for problem solving. Hence, we decided to share excerpts where these evidences were more apparent, above all the strategies related to *backward thinking*, *generalization*, *specialization* and *decomposing* (Polya, 1973).

While working with geometric modeling in technology-enhanced environments, students are faced with different construction procedures, compared to their physical modeling experiences, which are mainly caused by the features and constraints of the software. The different approaches to physical and digital modeling could offer opportunities for teachers and students to further their learning. In addition, modeling real world problems could enable connections and new perspectives between science and mathematics. Before discussing the analysis of these examples<sup>1</sup> we will outline the theoretical frameworks used for this work.

## **Theoretical framework**

The idea for this study was originally to develop geometric modeling from real and physical daily objects to investigate the ways they could foster mathematical exploration. As claimed by Carreira and Baioa (2015), students' behaviours in class usually do not reflect experimental sciences since they are not in the position to examine and interpret their surroundings mathematically.

Through this geometric modeling approach, we intended to enhance students' modeling competencies and mathematical thinking:

[...] to interpret a situation mathematically from iterative cycles of describing, testing, and revising mathematical interpretations as well as identifying, integrating, modifying, or refining sets of mathematical concepts drawn from various sources. (English, Lesh, & Fennewald, 2008, p. 8)

Considering the recent significant changes in mathematical thinking led by new technologies as well as social aspects such as communication and collaboration led by new technologies (English, Lesh, & Fennewald, 2008), we started this investigation under the lens of the instrumental genesis approach. We examined the transition of GeoGebra from an artifact to an instrument and later we witnessed practices emerged that could be explained by Polya's strategies of problem-solving, then how these strategies further assisted students in their instrumental genesis.

## **Instrumental Genesis**

According to Bussi and Mariotti (2008), Rabardel's instrumental genesis framework is based on the distinction between artifact and instrument. While the artifact can exist by itself, the instrument is a mixed entity with two components: the artifact produced for the subject, and the associated schemes of use. They are the results of a construction of the subject itself or of an appropriation of already existing schemes of use. The instrument describes an artifact and it is constituted in the use(s) that the subject develops. In this way, the uses of the artifact also depend on the needs and objectives of the user. According to Stormowski (2015) the importance of transforming a software, in our case GeoGebra, into an instrument is an evolution of the reorganization and modification of users' schemes, structuring of teachers' actions, and relations to mathematical concepts. In our particular case, participants had their strategies influenced by software outcomes even when such results were not exactly as they expected. As pointed out by Sinclair and Robutti (2012), if participants 'internalize' the use of a Dynamic Geometry Software (DGS) the artifact becomes a mean that offers

---

<sup>1</sup> The mentioned students' constructions are available online and can be utilized for other researches and teaching activities: <https://www.geogebra.org/m/Tng4JXDk>.

opportunities to solve problems. We observed that GeoGebra contributed to participants' reflections on simulation tasks and reorganization of their thinking schemes, as well as forming mathematical concepts. Nevertheless, these transformations were occasionally need to be assisted by teachers' external minimal guidance and supported by physical models.

### **Heuristic Strategies**

Polya's (1973) work on problem-solving listed a range of heuristic strategies that can be used to tackle a diversity of problems, not only restricted to mathematics. In our research, we consider "*the problem to be solved*" as the challenge to develop physical and digital representations as equivalent as possible. In this case, the seesaws' digital simulation was in the main focus of our investigation as we were already considering students' instrumental genesis with GeoGebra. For this purpose we have identified different strategies that were strongly connected to the geometric modeling approach: *guess and check*, *use of symmetry*, *draw a picture* and *be creative* to mention some of them. In the results section, we aim to outline more explicitly how some of these strategies connected the instrumental genesis with Polya's problem-solving. Stender and Kaiser (2017) state that there is little empirical research exploring how these heuristic strategies can be implemented in classroom teaching. They suggest that heuristic strategies can be transferred into strategic interventions by tutors. Through our current research and further results we intend to share geometric modeling tasks designs beyond teacher training programs. Once prospective teachers have the opportunity to experiment with different strategies with DGS they can feel more confident to reapply them in their teaching and encourage their students to carry out similar tasks.

### **Methodology and Methods**

The explorative nature of the study demanded an interpretative approach comprising qualitative methods as observation, data collection, and analysis (Cohen, Manion, & Morrison, 2011). Our experiments were carried out with 19 volunteer prospective mathematics teachers in Brazil and lasted a period of four months with meetings in every second week on average, to follow the evolution of the modeling process. All participants had already been introduced to GeoGebra during an introductory ICT course, where they explored the main software functions and features. For this experiment, students worked mostly in pairs and were assigned the task to build a seesaw using materials (e.g. wood, plastic, metal, etc.) of their choice. Then, they were asked to digitally model the same seesaw using a Dynamical Geometry Software.

The data collected in the initial part of the research came from three different sources: i) the digital modeling process of individual students or pairs was video-recorded; ii) the GeoGebra files were shared by students with the research team; and iii) an explanatory section, where participants presented their solutions based on their previous constructions was also video-recorded. In addition, all participants attended other four meetings with the whole group in order to expose their progress, exchange their ideas and discuss exercises with geometric modeling and joints.

### **Data Analysis and Results**

For the purposes of this paper, we will outline steps of constructing digital examples that we consider valuable to be supported by physical prototyping for learning. Through the connections of

both modeling approaches, participants first *worked backwards* to define the order of dependencies and the sequence of elements that they had to create. After students' trials they had to occasionally redefine the sequence of their constructions in order to obtain better results. This indicated that participants were constrained by the development processes and by their interactions with the software to rethink their strategies or "schemes of thinking". Both unexpected outcomes and inactivity from the software, due to for example inconsistent inputs, led students to rearrange their strategies of constructions. Valuable discussions arose from these experiments and often students had to re-evaluate their ideas and return *back to* basic mathematical *definitions*. Problem-solving strategies such as *generalization* and *specialization* were also recurrent in students' practices while sharpening their solutions<sup>2</sup>. The following examples aim to highlight the nature of the heuristic strategies utilized by students. They also offer some insights into how the use of these strategies makes physical and digital artifacts become instruments. In our first example, we examine the importance of using physical prototyping to trigger conceptual discussions about circles and tangents while students are digitally modeling the joints' movements. Such approach in this experiment encouraged students to make connections between the physical and digital models, using one of them to better understand the other. Figure 1 illustrates parts of this process.

**Figure 1: Physical and digital resources supporting participants' rethinking of their solution strategies**

After the first digital prototype of the seesaw was modelled, students were asked about the accuracy of their constructions. They were asked to identify and explain in which aspects their two models were, or were not, representatives of each other. Students identified that the ratio of the elements in the physical prototype was preserved in the digital model (Figure 1a). They also reported that the movements of the main seesaw board and the cylinder, on which the board should rotate, did not represent exactly the wanted physical movements. In their digital model, the board was intersecting the cylinder or (depending on how it was moving) the board and the cylinder did not even touch each other (Figure 1b)! While reviewing their digital model students felt the necessity to explore their physical model again (Figure 1c) to more concretely visualize movements and connections of the elements. In their words, they explained that: "ideally the main board is supposed to be connected to the cylinder, which should rotate around its axis of revolution." In continuity they should move from this "optical trick solution" to a most realistic representation. After few days they presented a new version (Figure 1d), in which they fixed the problem described above. They used

<sup>2</sup>*generalization*: circles and lines before arcs and segments;

*specialization*: board in a parallel position to the basis plane to rotate afterwards;

tangent lines to particular circles, which were obtained as a section of the cylinder and rotating the cylinder as the last step of the process. Therefore, the main board would stay connected.

The second excerpt brings another example of how the combination of digital and physical resources contributed to rethink geometric definitions in 3D space.

**Figure 2: Physical and digital resources enhancing proper meaning in 3D**

In a particular step of the construction<sup>3</sup> (Figure 2a), students needed to trace a perpendicular line passing through a point in 3D space and belonging to a given line ( $r$ ). However, while doing this, students were puzzled why GeoGebra did not trace such perpendicular line. When asked to explain why the software was inactive, they assumed that it was an operational problem. They repeated the same procedure twice without any result. Finally, students solved their practical problem using another line ( $s$ ). However, this was not enough for them to realize that they were skipping a “conceptual action mistake”. In order to give students some insights, the researcher suggested the use of concrete objects (Figure 2b). Part of this approach is registered in the following conversation:

- Student: What I can do is a perpendicular line to this one that passes here (the point  $Q_1$  that belongs to  $r$ ). [*There is no effect in GeoGebra.*]
- Researcher: Why do you think nothing happened?
- Student: I guess is because I’ve clicked on the wrong spot. [*He repeats exactly the same procedure and again achieved no usable results.*]

As a third attempt, they considered a different line ( $s$ ) that was convenient for his purpose and finally the perpendicular line emerged. Then the student continued:

- Student: Actually I was taking the wrong line, I guess.
- Researcher: What did you intend to do in the beginning?
- Student: Exactly like that, a perpendicular line passing through  $Q_1$ .
- Researcher: Ok, that is what you wanted as a final goal and you finally got it, but why it didn’t work on your first attempt?

After some new trials similar to the preceding ones and some vague conjectures, he finally said:

<sup>3</sup> Note that this screenshot is from a 3D representation, that means the lines  $r$  and  $s$  are not in the same planes. In this construction,  $Q_1$  belongs to  $r$  but not to  $s$ .

Student: I really don't know.

Researcher: Ok, go ahead. Let's discuss it later [...]

Student: The issue is that GeoGebra is quite intuitive, so you can get results through trial and error. Sometimes there is a hidden fundamental math principle, but you have been making so many constructions that you might eventually miss some math behind these constructions.

Interesting to note that even though the student was not able to identify the real reasons why he was stuck at this time, he recognized a consistent performance of GeoGebra and as a benefit for his learning due to GeoGebra's intuitive interface. At that moment the researcher felt the necessity to intervene with some pens to simulate, using physical objects, how the software was "thinking".

Researcher: Do you want to see something? [*The researcher hands him the pens and asks to represent a perpendicular line passing through a point belonging to another line*]

The student then immediately presented a possible solution.

Researcher: Is this one? [*Referring to the solution presented by him*]

Student: In order to obtain a perpendicular line it might need to pass through this point and make a right angle with the first one... [*He slightly rotates the second pen keeping the right angle*]

Student: [...]or like that maybe. [*He presents another solution*]

Researcher: But is there only one solution?

Student: Actually, not. I have thought about that. Somehow that is the reason it worked with the second line (the line that the point did not belong to), but not with the first one (the line that the point belonged to). If I had done it in 2D the software would understand that there is only one option (whether the point belongs or not to the first line).

The student's observation of linking 2D and 3D representations confirms that he realized that there was a significant difference between both 2D and 3D spaces. This is because the conditions to define a perpendicular line through a given line with a point lying on it were not properly the same. The transition from plane to space was quite recurrent among all participants and it happened as a natural step in the geometric modeling process. In particular cases, it was a bit conflicting when students kept the 2D concept, but ignored the new dimension in 3D. If something worked in 2D it did not necessarily work in 3D as well. In the previous example, the student realized the subtle difference caused by the new dimension in his solution after such interventions. Similarly as in the previous example, another challenging situation happened while the student was working with symmetry in 3D space. For example, students tended to use lines instead planes to reflect solids, which was misleading. This example was presented with further details in a previous paper (Lieban & Lavicza, 2017). The use of 2D geometry was useful in general as an auxiliary intermediate step in the construction of the seesaws. This process is what Polya labelled as *decomposing*, or splitting the problem into simpler steps. For instance, when students were struggling with reflecting solids,

they “reduced” the problem to a planar case and then continued with the extrusion afterwards. This change in strategy exemplifies the connection between the two theoretical frameworks. First students utilize the tool, which respond with an unexpected result by them, but through this process students operationalize the tool and it became an instrument. However, to be able to solve the problem they need to change their solution strategies. This is when heuristic strategies emerge, students start to decompose the problem and develop new solutions by using their instruments, but with subsequent steps from their decompositions. Another situation to exemplify the connection between theories happened when in the digital environment students had to define two points of a line as the ends of a segment in 3D space. They could do this construction directly with 3D features of the software, for example, spheres or circles with the normal (perpendicular to a plane) directions. While encountering such difficulties, they chose to use an auxiliary plane to continue the construction from this planar view as an alternative strategy. We present these steps in Figure 3, in which an auxiliary plane was used to construct a circle on it.

**Figure 3: Circles into 3D space as a tool to define distances**

Based on these examples, it can be assumed that the instrumental genesis and heuristic strategies can be combined to better understand student thinking. We observe that participants’ progress in their solution strategies and their schemes of using the software were triggered by the challenge to represent objects in 3D space and fixing this process through Polya’s *decomposing* strategy. The problem-solving approach by Polya seems to assist in the transition of GeoGebra from a tool to an instrument.

## Conclusions

Geometric modeling was applied in this research to investigate perspectives in teaching and learning of mathematics from real-life objects combining physical and digital resources. Several of Polya’s strategies are intuitively used when solving mathematics problems with DGS. To take further advantage of using the software it is important not only apply these strategies, but also identify, practice, and organize them. Nevertheless, it is important to emphasize that using the digital tools without constant reflections on various responses of the software can be difficult to achieve valuable learning outcomes. Thus, the assistance and supervision of teachers in such activities is crucial. In this study we observed the value of the use of physical simulation in supporting students to better comprehend and describe the action of joints as well to (re)interpret some mathematical behaviours often hidden while interacting with a software tool. The combined use of both physical and digital resources seem to bring a relevant contribution for refining students’ thinking and enhance their mental schemes or strategies during their geometrical modeling. With this approach, while hands-on prototypes were bound to physical barriers, digital representation helped to reinforce either geometric relationships or algebraic descriptions. The

outlined examples are only parts of a wider set of exercises and activities developed in our study. In future papers, we will report additional insights into connecting physical and digital modeling approaches.

*This paper introduces a definition of mathematical model which is intended to be applied in educational research. A synthesis of the background literature leads us to a notion of mathematical modelling that summarises contributions from a wide range of authors. This notion can be made operational in research by using the concept of mathematical model introduced in this study. This resulting proposal for defining model allows the establishing of suitable dimensions of analysis for research. The main features of this new conceptualization and its application to investigate mathematical models are also discussed.*

**Keywords:** *Mathematical models, problem solving, educational purposes, research tools.*

## Introduction

In recent years, the discussion about which capabilities are linked to the mathematical competence points towards modelling skills. These capabilities include not only knowledge related to mathematical contents, but also transversal competences such as problem solving, representation and connections (Montoya Delgadillo, Viola, & Vivier, 2017; Niss & Højgaard, 2011). Therefore, modelling is a focus of interest for researchers in mathematics education (Carreira & Baioa, 2017). A great number of authors have addressed this issue from a wide range of perspectives.

Our synthesis of the different approaches reveals five features that describe how educational researchers understand mathematical modelling: (i) Modelling is a student's activity. Indeed, Chevallard, Bosch, and Gascón (1997) stated that mathematical knowledge is a human activity and, as a part of Mathematics, so is modelling. What is more, they emphasised that a great part of all mathematical activities can be understood as modelling activities; (ii) Modelling is connected to a problem originated from a certain system. In this regard, Castro and Castro (1997) identified “modelling” and “problem solving”, whereas other researchers claimed that the purpose of modelling is to produce knowledge about the studied system (Chevallard, 1989). A third group distinguished between modelling “for”, if the purpose is to solve a problem, and modelling “of”, if the purpose is to generalise to produce knowledge (Streefland, 1985); (iii) Modelling entails a process, i.e., modelling follows a sequence of steps that individuals carry out when tackling a problem. These steps can make up an ideal cycle (Blum & Leiß, 2007; Borromeo Ferri, 2006) or just a set of activities (Ärlebäck, 2009); (iv) Modelling drives students to acquire mathematical skills. On this point, Niss and Højgaard (2011) understand modelling as a competence to be developed in school. Likewise, Blomhøj (2004) interprets it as a teaching practice that links real world and mathematics. Further, García, Gascón, Higuera, and Bosch (2006) pointed to a double didactic power of mathematical modelling, namely that it can be used to teach mathematical contents, or it can constitute the objective of learning; (v) Modelling leads to the construction of a model, which is the product of modelling

(Sriraman, 2006). In this sense, modelling means a translation between real world and mathematics (Blum & Borromeo Ferri, 2009) or between different mathematical domains (García et al., 2006). The discussed five features above allow us to understand modelling in mathematics education as *the activity that entails the development of some mathematical skills, originating from a question within a system and is carried out during the process of design, application and evaluation of models. These models allow the use of mathematics to produce knowledge about the system.*

### **Importance of the concept of model and research question**

The synthesised notion of modelling given above relies on several ideas that researchers must specify depending on their goals: What kind of *skills* are entailed by modelling? Which activities are related to *the process of design, application and evaluation*? What is a *model*? As commented on above, there is an extensive literature addressing the process and competencies associated with modelling (see Kaiser, 2014 for a review). Nevertheless, there is a lower number of papers addressing the analysis from the notion of model. The importance of having an operational definition of model is crucial for research purposes. Firstly, it allows focusing the research on the actual model whenever the whole modelling process is inaccessible or too complex to analyse. Secondly, it also provides what elements to focus on when analysing a mathematical model, and which in addition is also useful when discussing other dimensions of modelling.

In this context, the research questions addressed in this paper are: Which elements comprise a mathematical model in the framework of modelling outlined above? Can these elements make up a functional definition of mathematical model? With the aim of answering these questions, we now turn to discuss and elaborate on the main features of the preceding discussion.

### **Definition of mathematical model for research**

#### **Background and relevant items**

The importance of lending meaning to the term “mathematical model” has been discussed in the past years. Even though almost all the authors share the intuition of a model as a mapping between a system and a mathematical structure enabling to answer questions or get information about the system, there is no agreement on the nature of mathematical models or what their key components are. An early explicit definition of mathematical model was proposed in the context of engineering (Minsky, 1965). Under this approach, a model is a supporting decision-making tool. This pioneer idea focuses on the usefulness for the system but is far away from being functional for research. However, it contains the first relevant item to define a model up: the analysis of a problem within a system. Connecting back to mathematics education, Lesh and Harel (2003) proposed a notion of model which was based on two components: a mathematical conceptual system together with its accompanying procedures. Both components are expressed through different representations in order to solve a problem. Lesh and Harel complementary perspective is more aligned with the purposes of our paper, which from our point of view stresses two elements that must be considered in educational research: a mathematical description of a problem and the representations that allow working with that description to solve the problem. Niss (2012) defined the term mathematical model without associating it with a problem through the triplet  $(D, f, M)$  that connects an extramathematical domain  $(D)$  with a mathematical realm  $(M)$  via the “mathematisation” mapping  $(f)$ . Niss’ definition included

the domain as a part of the model and also objectified the intuition of the mapping that links the system with mathematics. However,  $f$  is not always easy to use in analysis. Sometimes it is quite difficult to find the D-M-correspondences because the objects/variables of interest might be implicit (e.g. the best value for money in the second example below). In other cases, the key point of the model does not rely on the connection but in the use of mathematical properties (the extensive nature of area in the first example). Velten (2009) avoided the mathematisation mapping by defining a mathematical model using another triplet,  $(S, Q, M)$ , but with a different interpretation:  $S$  is a system,  $Q$  is a question related to  $S$  and  $M$  is a set of mathematical statements that can be used to answer  $Q$ . As with Niss' definition, Velten's approach provides suitable categories of analysis, but it focuses on a problem and does not (explicitly) take representations into account.

The synthesis of the ideas explained above stress the following key features of a mathematical model: (i) that a model is determined by a set of specific components, that lead to define suitable categories of analysis; (ii) that a models is associated with a system (instead of a problem); (iii) that a model includes a mathematical structure that allow working with the model; and (iv) that a model includes representations. Our integration of these features gives rise to the new definition of model we propose below and which we suggest being used for research in mathematics education.

### Definition of model

A mathematical model is a triplet  $(S, M, R)$ , where

- $S$  is the *system* the model is concerned with. It consists of a set of objects, their properties, and the relationships between objects and properties.
- $M$  is the (conceptual) *mathematization* of the system, i.e., the set of mathematical concepts and properties that abstract the relevant information from  $S$ , along with the set of relationships applied to produce mathematical knowledge from the system.
- $R$  is the set of mathematical *representations* of the system. It contains the explicit representations that enable to work mathematically with the elements of  $M$  and, thus, produce knowledge about the system.

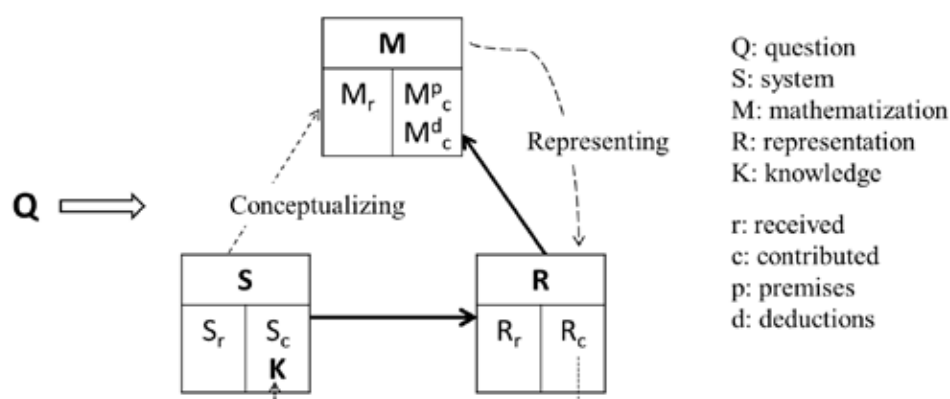

This definition is constructed from three inseparable components that show different levels of abstraction  $S$  is real (as well as the context in which the system is framed), but  $M$  is purely conceptual, so it is inaccessible and usually not evident. It is necessary, therefore, to use  $R$  (observable) to describe and work with the model. Figure 1 represents these levels and two types of connections between the components of a mathematical model, which are discussed below.

### Categories of analysis

The main characteristic of this definition is its functionality, since it allows establishing categories for the analysis of mathematical models produced in educational contexts. In order to provide a complete view of what a model creator (the research participant) contributes, the analysis based on the triplet  $(S, M, R)$  may be decomposed into two parts. The first part is composed of the elements received by the model creator, that is, the explicit information he/she receives (the enunciation of a task, for example). The second part is constituted by the elements contributed by the creator, which may include identified objects in, or hypothesis about,  $S$ , latent concepts or relationships of  $M$ , or

new representations incorporated in R in order to generate knowledge by working mathematically. It is of interest to specify two subcategories of contributed elements within the mathematization (M) component: (i) premises, which are mathematical statements used without justification (they might be explicit or latent and made visible through R); and (ii) deductions, which are those statements justified by an explicit rationale. These categories are not exhaustive, since one can find contributed elements of mathematization that are neither premises nor deductions (see the examples below).

The argument above give rise to six categories of analysis: system received ( $S_r$ ), mathematization received ( $M_r$ ), representation received ( $R_r$ ), system contributed ( $S_c$ ), mathematization contributed (with premises  $M^p_c$  and deductions  $M^d_c$ ) and representation contributed ( $R_c$ ). These are the elements of the mathematical model to be studied. The categories induce a first stage of analysis (the description of what model creator has received) and a second stage of analysis of what he/she has contributed. In addition, within the analysis of a model, an S-R-M natural strategy emerges, so that the researcher can obtain complete information about the model by (i) paying attention to the involved elements of the system S, then (ii) focusing on the representations R and finally (iii) analyzing the conceptual mathematization of the system M. This analysis sequence deviates from the order of the components (S, M, R) in our definition. The sequence S-M-R was chosen for the definition since it evokes the ideal mental process of building a model. Components of the model may be described following this procedure (Figure 1).

**Figure 1: Scheme of the proposed model concept. Note that the analysis strategy (continuous line) and the mental process that generates the model (dashed line) follow different trajectories**

## Application of the proposed definition: The analysis of school models

### Two practical examples
